

Fig 7 Disability to parts of arm each having specific award.

bearing and power of action in standing walking running or jumping (4) security or reliability of toe, heel or foot action in habitual and technical accomplishments of life long development, (5) endurance of gripping power of toes, toleration of continuous action.

The method is graphically presented in Figures 1 and 2

The scale of the rule is graded as follows

Quickness of action	value 10 per cent
Co-ordination of movements	value 20 per cent
Strength	value 30 per cent
Security	value 40 per cent
Endurance	value 50 per cent
Safety factor	value 60 per cent
Prestige of normal physique	value 70 per cent
Total	100 per cent

In making an estimate of the extent of disability the percentage of loss of each functional factor is conceived from the standpoint of medical knowledge and the result is expressed in terms of disability.

For instance, if it is thought the activity factor will be affected 25 per cent, then 25 per cent of 10, the value of the factor means a 25 per cent disability. Applying the test to each of the factors in the 100 per cent scale on the so-called measuring rod of function and summing up the percentage of loss of each factor the total amount of disability is determined. For example, a back disability might be conceived as illustrated in Figure 3.

If a disability to an arm has occurred, such as a limitation of motion at the elbow the same principles, on the measuring rod, are applied. For example, an estimate might be applied as in Figure 4.

Multiple disabilities often are very troublesome in that the physician may be asked what percentage each contributes to a disability. These may be estimated as illustrated in Figure 4.

Another troublesome phase of estimating disability is that in which each individual disability to a part is so great that the sum of all disability percentages would be more than 100 per cent. The methods of calculating such a case is illustrated in Figure 6.

In many States the law awards a certain amount for loss of individual parts of the body such as a finger, hand, arm or foot. Where a disability has occurred to several parts of an extremity as in the finger, hand, and upper arm, it is sometimes rather difficult to express in proper percentage the disability each part is to the entire arm. The method of estimating such disabilities is illustrated in Figure 7.

TRIVIAL INDUSTRIAL INJURIES OF THE HAND LEADING TO PROLONGED DISABILITY

ALLEN B. KANAUEL, M.D. CHICAGO

IT is unfortunate that many patients with trivial injuries do not apply at once to their physician for proper treatment. Too often the surgeon sees patients who have sustained simple injuries of the hand which if they had been treated promptly and properly would have given rise to no disability or trouble. Many patients who now have useless hands would have been spared this disability had small pin and needle punctures, scratches, and bruises been properly treated, if such injuries had been properly cleansed and treated with antiseptics and kept clean.

Among these, attention may be drawn to infection from cattle hairs. These occur most commonly in those dealing with cattle, such as stockmen, those milking cows, etc. The hairs of cattle have scales that tend to migrate under the skin when they have entered through some cracked callos. These patients develop minor abscesses which, if opened, tend to be followed by repeated abscesses and disability often extending over a period of months. If the abscesses are

properly opened and all the migrating hair removed there is prompt recovery.

Another minor injury almost always neglected is that due to indelible pencils for example, an office worker breaks off the point of an indelible pencil in the palm, the point remaining in the tissue. At times nothing is done, and at other times inadequate attempts are made at removal, with the result that the indelible lead is crushed. After this, although no difficulty may be experienced for several days, chemical action of the dye may take place and cause the death of the tissues around the pencil point puncture and infection may ensue. Such patients may have serious disability lasting for weeks and months and suffer great pain and discomfort. If a surgeon had been consulted he would have removed at once and completely the destructive indelible point. In the public schools in Germany indelible pencils are now forbidden to children, to safeguard them against the loss of eyes from injury of the conjunctiva from such pencils.

THE PROBLEM OF COMPETITION IN INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

H. J. WHITACRE, M.D., TACOMA WASHINGTON

THE time-honored and highly commendable ambition of every educated physician to develop a practice upon a basis of his opportunity to use his assets in service to society has been seriously thwarted in the state of Washington. This has been brought about by that form of health insurance known as contract practice.

Industrial accident insurance was first established in Washington to make it possible to render proper medical and surgical service to the workers in remote lumbering camps. Later this plan for paying for such service was adopted in cities and towns. Contract practice likewise followed this plan into the urban communities with the result that in the concentration of such surgery in the hands of a few physicians who seek these contracts the methods of securing this work are not always within the bounds of fair and ethical competition.

The medical profession did not resent industrial insurance or contract practice seriously as long as contracts were confined to industry and large groups of workmen. The object is to the employment of lay solicitors to comb the community extol their employers and sign up small groups in all walks of life. One such contracting physician is operating this system over a radius of 30 miles and this area includes large cities.

A commendable and necessary method of rendering medical care in remote industrial regions has been transformed by commercial methods into a gigantic health insurance movement that threatens to include the entire population, and the general medical profession is very properly alarmed.

Some have advocated the expulsion of contract doctors from our medical societies. Others have urged the passage of laws forbidding contract practice. Neither position is tenable.

Counter movements initiated by groups in medical societies have not always been successful for obvious reasons.

Eighteen months ago the physicians of Tacoma established a research laboratory for the study of medical economics, and industrial medicine in its relationship to the general problem of state

health insurance has been the major problem studied.

Contract practice is legal in the State of Washington.

Organized labor is opposed to contract practice and most of our physicians even those who hold contracts do not like this method of practicing medicine but both the preference of employers for this system, and the need of industry for some form of accident and health insurance have woven it firmly into the industrial fabric of the State of Washington. We must deal with it. We are not opposed to health insurance as a principle.

We are opposed to the evils which have crept in as the details of the system have been applied and believe that the medical profession should furnish the leadership for a movement to develop a better form.

The Tacoma group have done some intensive work on a plan for handling the situation in Tacoma. The causes of failure in other groups have been largely professional shortcomings and the entire group has now agreed to submit to rigid rules and regulations for their elimination.

We have tightened control by giving autocratic power to a committee of three. Each new case must be promptly reported to the office of the bureau, a case record must be set up, and the executive committee must review the file daily. This committee has the authority to call a consultation on any serious or prolonged case and the consultant must file a written report of the consultation at the bureau office. Bills may be modified or disallowed. State and insurance reports are sent through the bureau office and it is the duty of the manager to see that they are promptly and properly completed. The bureau or in other words the organized profession stands behind the quality of service rendered.

An experiment in a department store has shown that one dollar per month per person is not sufficient to render adequate medical service. The amount necessary is from one dollar and fifty cents to two dollars per month.

On the whole the plan of the Tacoma group is working well under the strict regulations.

CONFERENCE ON TEACHING OF SURGERY

GRADUATE AND UNDERGRADUATE TEACHING

THE personnel of the Committee on the Teaching of Surgery and Surgical Specialties is as follows: Fred C. Zapffe, Chicago, chairman; Elliott C. Cutler, Cleveland; Irving S. Cutler, Chicago; George J. Hexter, New York; Alexander R. Munroe, Edmonton; Allen O. Whipple, New York. The conference on this subject was held at the Jefferson Hotel, St. Louis, October 19, 1935, as a part of the Clinical Congress of the American College of Surgeons. Dr. C. Gordon Hayd, New York, vice-president of the American College of Surgeons, presided.

FRA KLIN H. MARTIN, director general of the American College of Surgeons, explained the reasons for the active interest of the College in the subject of teaching of surgery and the surgical specialties in the following terms:

Why does the American College of Surgeons seek co-operation with the Association of American Medical Colleges? Because it is a paramount aim of the American College of Surgeons to improve surgery that is necessary and to eliminate unnecessary surgery. If this program is to achieve its greatest development the American College of Surgeons must have an interest in every branch of medicine. It must co-operate with the approved medical schools where medicine is taught; it must co-operate with the approved hospitals, the environment in which doctors and surgeons treat the ill and injured; it must co-operate with the scientific development of general, special, and applied science and it must co-operate with the public on the basis of the ideals and ethics of the most learned profession.

There are in the United States about 145,000 registered scientific physicians. Approximately one-fourth of this number are engaged in public health activities, and another one-fourth have retired and are not now engaged in the active, independent practice of medicine. This leaves a total of some 75,000 doctors who are practicing independent preventive and curative medicine in personal health. It is therefore apparent that the American College of Surgeons—consisting of 10,849 practicing surgeons joined in a strong administrative corporation—is in a position to co-operate closely with your influential body that is so deeply interested in the guidance of the teaching of all branches of medicine and surgery.

Particularly are we interested that the scientific medical profession shall maintain the purity of its ranks—that it shall be kept free from the encroachments of irregulars, cultists, and patent medicine vendors.

We are anxious that medical graduates who are serving as internes in our hospitals shall be protected from the subtleties of politics and irregular associations—that any hospital shall be ineligible for interne assignments if it is loose in its ethics. If it tolerates irregular financial practices among its medical staff. If the staff conferences are neglected or actually repudiated and ignored, and if indifferent records and perfunctory laboratory reports are countenanced.

The College has worked conscientiously to eliminate these irregularities from hospital conduct. Each year the approved list of hospitals embodies such institutions as are found eligible after careful personal survey by a representative of the College. This list is in your hands. The dean of every Class A medical school possesses that record, and he can readily ascertain from us why any particular hospital is not on that list. If we can be shown that we have erred in our judgment in eliminating a hospital, we will be glad to make amends.

The paramount object of this yearly conference is to encourage a discussion of our mutual activities, and to lead the sympathetic influence and co-operation of the American College of Surgeons to the word of your Board, and to the medical schools which have the responsibility of educating the doctors of the future.

FRED C. ZAPFFE as chairman of the Committee spoke of the formation of the Committee and its purposes and stated that the Committee wished to secure the opinions of all teachers of surgery and to present them in a report which will be helpful to teachers of surgery in rebuilding their corner.

GEORGE J. HEXTER's paper on "Graduate Teaching of Surgery" was presented, in his absence, by Dr. Zapffe. Dr. Hexter expressed the opinion that the opportunities for graduate instruction in surgery in this country are inadequate and that they could and should be increased, not only in the medical schools but possibly in the larger and more important hospitals. Dr. Hexter had sent out a questionnaire and analyzed the type of graduate teaching in 24 medical schools. In these schools graduate teaching in surgery takes the form of resident or fellowship systems, with a variable time in continuous residence in a teaching hospital where the experience includes surgical pathology, surgical diagnosis, pre-operative and postoperative course of surgical patients and a variable amount of operative experience gained at first as an assistant, then as an operator under supervision, and finally as an independent surgeon. These courses of instruction vary from 1

to 5 years and are not uniform in amount of time devoted to the various subjects or in the subjects covered. A number of the schools giving such courses grant degrees upon their satisfactory completion. Of the men who have taken such courses the majority have positions of professional or other rank in the country. The favorable opinion of the heads of the departments of surgery in certain medical schools toward such a course of instruction was expressed.

ELLIOTT C. CUTLER's paper on Undergraduate Teaching of Surgery was presented by Dr. Zapffe. As a result of the questionnaire sent to leading surgeons teaching surgery in the United States the trend of opinion was expressed as being that these surgeons emphasized the type of the principles of surgery surgical pathology a course of minor trauma and sepsis and surgical diagnosis. These same men have indicated strongly that they do not think it within their province to teach operative surgery. Dr. Cutler emphasized the desirability of realization on the part of the medical schools and licensing boards for the necessity of an extra and special training before medical graduates are allowed to assume responsibilities attendant upon the individual practice of surgery.

ALEX O. WHIPPLE presented his paper on Post Graduate Instruction in Surgery. Dr. Whipple stated that the successful development in the organization of adequate and modern medical service in any community depends upon the training the ability and the experience of the professional personnel. The proper allotment of time and the graded sequence of the periods of training required in the various fields of medicine and the specialties are the factors which have to be considered in the pre medical school, medical school hospital in ternship residents hip or fellowship up to and including post graduate courses for those already trained in general medicine or the specialties. These are but phases of the entire scheme of medical and

surgical training. Dr. Whipple emphasized the fact that post-graduate courses in surgery and surgical specialties should be limited to candidates with adequate surgical training and with some experience in surgical practice. Such courses should be properly organized and conducted by senior and more experienced surgeons preferably under university auspices. In such courses the advantages were pointed out of diagnostic clinics follow up clinics, laboratory courses courses in roentgen film and fluoroscopic interpretation, courses in endoscopy and experience gained by close association with the teaching surgeons.

ALEXANDER R. MUNROE presented the 'Amendment to the Medical Profession Act of the Province of Alberta of 1926' which prescribes qualifications for those who practice surgery in that Province. The qualifications are fulfilled under the auspices of the Senate of the Provincial University. During the past 6 years, 83 certificates in general surgery and surgical specialties have been granted.

The discussion of these subjects was continued by Drs. Howard C. Naffziger Samuel C. Harvey Owen H. Wangenstein George W. Crile, and W. T. Coughlin. Dr. Harvey drew attention to the necessity of producing men with initiative enough to go on learning surgery the rest of their lives and to the fact that to accomplish this a modern system of apprentice assistants would be a desirable method. Dr. Wangenstein expressed the opinion that so many already trained surgeons are now generally available that the minimal requirements of training for the practice of surgery should be clearly defined and he emphasized the importance in surgical training of experience in other than operative procedures. Dr. Crile explained that all of the activities of the American College of Surgeons are part of a great educational program and indicated that it was fitting that such an institution display a great interest in the facilities available for the training of surgeons and surgical specialists.

COMMITTEE AND DEPARTMENT REPORTS

DEPARTMENT OF CLINICAL RESEARCH—ALBERT J OCHSNER MEMORIAL

THE work in clinical research, which is being conducted by the College includes that of the following committees: committee on the treatment of malignant diseases; committee on the archives of malignant diseases; committee on bone sarcoma; committee on the treatment of fractures; committee

on clinical laboratories; board on medical motion pictures; board on industrial medicine and traumatic surgery.

A survey of the work of this department which has been performed during the past year is embodied in the reports of the individual committees.

COMMITTEE ON THE TREATMENT OF MALIGNANT DISEASES

ROBERT B GREENOUGH M.D. Boston Chairman

I HAVE the honor to submit the following report of the Committee on the Treatment of Malignant Diseases.

The subject of cancer clinics has been actively promulgated during the past year by personal interviews with the administrators and medical staffs of hospitals. For this purpose the Director General has assigned the co-operation of the hospital investigators and in addition two special field representatives.

It is obvious that there are hospitals on the approved list of the College in which it would be inappropriate to have cancer clinics, such as in many of the hospitals of the federal government, in the hospitals for children, and in maternity, orthopedic, tuberculosis, mental, convalescent, contagious diseases, industrial, and eye, ear, nose and throat hospitals. But in every hospital into which cancer cases are received there should be facilities and personnel for efficient diagnostic and therapeutic measures, and this implies consultations or conferences between trained surgeons, radiologists, and pathologists.

In some hospitals it happens that there is one individual member of the staff or one department whose special interest in cancer has led to an unusually good organization for the care and follow up of cancer cases in that department. Such hospitals are recognized in the listing of the College by a special designation referring to the departmentalization of the hospital and the existence in one or more of the departments of the equivalent of the minimum standard for cancer clinics.

From other hospitals or clinics evidence has been presented to the College that the required facilities and personnel are available but that completion of the organization of a formal clinic along the lines

recommended by the College has not yet been accomplished. Such institutions will have appropriate recognition in the listing of the College.

In certain clinics in medical schools, and in certain rural hospitals, the function of the cancer clinic is restricted to that of providing diagnoses, whereas the therapeutic measures are carried out in completely equipped institutions to which the patients may be referred. Such diagnostic clinics should attain appropriate standards and will receive recognition in the listing of the College.

It is proposed that a list of approved cancer clinics be published in 1933. The hospitals that have been personally surveyed or from which adequate reports have been received during the past year number one thousand fifteen. Of these seven hundred two have no cancer clinics. A tentative classification of the cancer clinics follows:

Approved	130
Recommended	53
Organizing or contemplated	155

At the meeting of the Committee one year ago eleven additional record forms for cancer of different parts of the body were approved and extensive circulation has been given to these record forms which now number sixteen. During the year two new record forms have been prepared and others are in the course of preparation. The widespread adoption of these forms will do much to facilitate the compilation of reliable statistics on the subject of cancer in America.

In continuance of the previous work of the Committee, all Fellows of the College and Members of the Radiological Society of North America were invited during the month of May to register with the Committee all cases of cancer occurring in

their practice during the years 1924-25-26. As a direct response to this request there have been received thus far 2,365 detailed records of cancer of different parts of the body, included among which are 1,020 of 5 year survivals. These records are being subjected to careful analysis for grouping as to organs types of cancer methods of treatment and results, and the information will be tabulated and published with the three thousand detailed records previously in the archives of the Committee.

The recency of any general movement for the organization of formal cancer clinics and their more accurate records has impeded the work of the Committee in the collection of statistics of greater volume.

An important result of this widespread request and the distribution of record forms has been the known installation of improved record systems by many hospitals so that in the future compilation of results will be much facilitated. Many who signified their willingness to co-operate in this study found it impossible on account of incompleteness of their existing records, and have now installed new record systems.

The College engages in these cumulative studies for the benefit of its Fellows and of humanity, and it will accomplish its purpose only when its Fellowship in its entirety approves and participates in such studies. These studies by the committees and by the administrative officers constitute merely a means of expressing the voice and work of the Fellowship of the College. On the other hand it is the duty of the committees and the administrative branch of the College to indicate to its Fellows methods and studies that will lead to progress in knowledge and in its application. In no small degree this purpose has been accomplished by the inauguration of the work directed toward the compilation of reliable statistics.

In addition to this work more attention has been directed toward the compilation of cumulative statistics from authenticated recent reports in the literature. Based on a study of this literature which has been compiled by the College Dr. Grantley W. Taylor prepared an article on Cancer of the Breast which was published by the College. Similar publications on cancer of other organs are contemplated.

Minimum Standard for Cancer Clinics in General Hospitals

1. **Organization** There shall be a definite organization of the service and it shall include an executive officer and representatives of all the departments of the hospital which are concerned in the

diagnosis and treatment of cancer. The services of a secretary and of a social service worker shall be available.

2. **Conferences** As an essential feature of the service there shall be regular conferences or consultations at which the diagnosis and treatment of the individual cases are discussed by all members of the clinic who are concerned with the case.
3. **Patients** Reference to the cancer clinic of all patients in whom the diagnosis or treatment of cancer is to be considered shall be either voluntary or obligatory in accordance with the vote of the medical staff or of the governing board of the hospital.
4. **Equipment** In addition to the diagnostic and therapeutic surgical equipment which is required in every approved general hospital there shall be available an apparatus for X ray therapy of an effectiveness which is generally agreed upon as adequate and an amount of radium sufficient to insure effective treatment.
5. **Records** In addition to the records which are required in every approved general hospital, there shall be additional records of (r) the details of the history and of the examination for cancer in different regions of the body, such as are indicated on the form records which are recommended by the Committee on the Treatment of Malignant Diseases American College of Surgeons (b) the details of the treatment by radium or X ray as indicated on the form records which are recommended by the Committee on the Treatment of Malignant Diseases American College of Surgeons (c) periodic examinations at intervals for a period of at least five years following treatment.
6. **Treatment** The treatment of cancer patients shall be entrusted to the members of the staff of the cancer clinic except in cases in which adequate treatment in accordance with the collective recommendation of the staff of the cancer clinic can be procured otherwise.

The personnel of the Committee on the Treatment of Malignant Diseases is as follows:

Robert B. Greenough, Boston, <i>Chairman</i>	
A. C. Broders, Rochester, Minn.	John M. T. Finney Baltimore
Curtis F. Burman Baltimore	Burton J. Lee, New York
George W. Crile Cleveland	Frank W. Lynch, San Francisco
Bowman C. Crowell, Chicago	Robert T. Miller, Jr. Baltimore
William Duane, Boston	Henry K. Hancock, Philadelphia
Edwin C. Ernst, St. Louis	H. Gleason Wells, Chicago
Rupert H. Fike, Atlanta	Francis C. Wood, New York

COMMITTEE ON THE TREATMENT OF FRACTURES

CHARLES L. SCUDDER, M.D. Boston Chairman

I HAVE the honor to submit to the Board of Regents the ninth annual report of the Committee on the Treatment of Fractures. There are now 39 members of the General Committee.

The death of a former member of the committee, Dr A. P. C. Ashhurst of Philadelphia and the death of an active member Dr Nathaniel Allison of Chicago are recorded.

A revised and amplified second edition of *An Outline of the Treatment of Fractures* has recently been published by the College. The cordial reception of the first edition of this *Outline* by the profession has more than warranted the time and expense spent in completing this second edition. To Dr Roscoe Webb of Minneapolis Dr Edwin Ryerson of Chicago and the director of the Department of (Clinical) Research Dr Bowman C. Crowell, the appreciation of this Committee is extended for their supervision and conduct of this second edition. The Committee hopes to keep this *Outline* abreast of any important advance in the treatment of fractures. New printings from time to time will be made. It is the desire of the Committee to keep those members of the American College of Surgeons who are especially interested in fracture treatment periodically informed of progress in this special department of surgery. Copies of this *Outline* may be had by addressing the American College of Surgeons, 40 East Erie Street Chicago Illinois.

Regional committees. It has been from the beginning and still is the policy of the General Committee to extend the influence of the College through the living personal contacts made by membership of surgeons interested in fractures in these regional groups. There are now twenty-eight such Regional Committees. We have, therefore at present about three hundred men carrying the ideals of the College directly into their several committees. The Committee believes that an immediate formation of new committees should be undertaken. Each state should have one or more active regional groups. Many applications have been received from different parts of the country for the formation of these local committees.

Industry is demanding that which the Committee on the Treatment of Fractures is prepared to deliver. It is strongly urged that the Department of Clinical Research make an immediate response to this demand.

In order to facilitate the work of these regional groups the College will soon publish in mimeographed form the reported activities of all existing regional committees.

Sub-committees. Steel Bone Plates and Screws. Committee Philip D. Wilson W. O'Neill Sherman Norman T. Kirk Wm. L. Keller. On June 18 1931 a general conference of representative manufac-

turers, distributors, and users of steel bone plates and screws adopted a commercial standard for this commodity. The industry here has since accepted and approved for promulgation by the Department of Commerce through the Bureau of Standards, the commercial standard. The standard became effective for new production on November 16 1931.

The general conference voted the establishment of a standing committee. Dr P. D. Wilson, chairman sub-committee American College of Surgeons. Dr J. F. Barry Veterans Administration. Dr J. F. Cochrane, Kny-Scheerer Corporation, Captain E. J. Gow Navy Department. Major N. T. Kirk, Walter Reed Hospital. Harvey R. Pierce, Harvey R. Pierce Company. Charles J. Pilling, Gen. P. Pilling & Sons Company. John M. Smith, American Hospital Association. F. W. Reynolds, secretary Bureau of Standards.

The normal interval for revision of the standard is set for one year. Acceptances of the standard established were received from associations, firms, hospitals, and surgeons, and from government departments. The door to progress remains open through the existence of the permanent committee.

The Sub-Committee on Medical Education. Wm. Darrach, Frederic J. Tees, Isidore Cohn, George A. Leland, Jr. and Clay Ray Murray. Most of the medical schools of the country have reduced the number of hours in their undergraduate curriculum. As a result in many special fields of medical work, the undergraduate instruction has become of necessity limited very largely to a thorough understanding of general principles followed by an opportunity to apply these to individual cases under the direction of a teacher. As a result of this, it has become of increasing importance that those responsible for the undergraduate teaching of fractures should concentrate their efforts on formulation and explanation of broad general principles. To make up for the lack of undergraduate teaching it is of great importance that in each hospital at least one be made responsible for the careful training of an intern staff in this field. Moreover the need for the establishment of opportunities for the practicing physician to refresh or increase his knowledge in the treatment of fractures has become much greater. It is therefore recommended that

1. Even greater stress be placed on instruction in the pathology of fractures, the process of repair and the broad general fundamental principles of treatment.

2. Each hospital, whether it contains a special fracture service or not, appoint someone who shall be responsible for the training of internes in the treatment of fractures.

3. Wherever possible opportunities for continued education for graduates in medicine be established.

both in teaching hospitals and under the auspices of the various medical societies.

The sub-committee reported in detail the methods in use at Columbia University in teaching the treatment of fractures to undergraduates. Graduate teaching is also being handled by this committee.

The sub-committee is in touch with the several groups interested in medical education in the United States especially the Council on Medical Education of the American Medical Association, The Association of American Medical Colleges, the Commission on Medical Education, and the Committee on the Teaching of Surgery of the American College of Surgeons. It is hoped that a further consideration of undergraduate instruction in fracture treatment may be secured.

The sub-committee has communicated with those bodies having in charge the examinations of graduates of medical schools for licensure to practice medicine. It has been thought that the Educational Committee might propose to these bodies the National Board of Medical Examiners, and through this group to the various state examining boards the general scope of questions to be asked the recent graduates of medical schools so that pressure may thus be brought to bear in a perfectly legitimate fashion upon the undergraduate school to produce well informed graduates in these fracture matters. These groups are vitally interested in similar problems.

A letter was sent to the National Board of Medical Examiners asking if they would accept suggestions regarding questions on fractures which the National Board would ask. A favorable reply came from the Board desiring to co-operate with this committee. The Federation of State Medical Boards is associated with the National Board of Medical Examiners. A letter from the secretary in Des Moines states that they are in full agreement.

The Sub-Committee on Physical Therapy. Fred Eric J. Cotton, H. Earle Conwell, Clay Ray Murray. This committee is preparing a carefully edited statement of the status of physical therapy in the care of fractures.

The Sub-Committee on the American Railway Association. The Permanent Committee on Fractures of the Medical and Surgical Section of the American Railway Association made a very constructive report at the May 1932 meeting in New York. This covered (1) first aid instruction to employees of railway companies (2) co-operation with the Fracture Committee of the American College of Surgeons in the matter of improving the treatment of fractures—in the adoption of "An Outline of Treatment" when published (3) X-ray reports as practiced by one of the members, R. C. Webb, chief surgeon of the Great Northern Railway. The X-ray suggestions were the same as those in "An Outline of Treatment" recently published.

Addresses were made by Mr. E. H. Kimball, claims attorney for the Great Northern Railway

editor of the *Bulletin of the Association of Railway Claim Agents* also Mr. Winter, claim department of the Chicago Northwestern Railroad. The Association of American Railway Claim Agents will soon co-operate formally by appointing a committee.

The Sub-Committee on Ambulance Equipment and First Aid. Robert H. Kennedy, chairman, Philip H. Kreuscher, W. L. Keller, Hubley Owen. This committee has reported a definite program which is being carried out and it is hoped will extend to every center in the United States. The move has already begun in New York City and has extended to Philadelphia. Throughout the west funeral homes and undertakers provide the ambulance service for doctors. Relations have been established with the National Association of Funeral Directors and it is hoped that they will consider the idea of equipping ambulances and instructing the drivers of ambulances along the lines formulated by the committee.

The Sub-Committee on American Red Cross. The committee has completed its contribution to the first aid work of the *American Red Cross Manual*. This *Manual* is now being printed and a new edition is soon to appear containing these suggestions. The committee is thus in touch with the many first aid classes of the American Red Cross throughout the United States.

The annual Fracture Oration last year was given by Dr. Wm. Darrach, professor of clinical surgery of Columbia University. This year the Oration is to be given by Dr. Philip D. Wilson of Harvard University.

The committee is active in furthering in every way possible a better treatment of fractures.

Standard for Minimum Equipment for Fracture Treatment in Hospitals

- 1 That all general hospitals be equipped to care for fractures that the minimum equipment for the transportation and emergency treatment of fractures be the following or its equivalent:

Thomas upper extremity splints, Thomas lower extremity splints with traction straps, slings and buckle straps, Hodgen splints, cast splints, assorted sizes, Cabot wire splints, straight pieces of wood (of assorted length, width and thickness) for splints, plaster of Paris bandages, some form of overhead frame for suspension, suitable X-ray apparatus, including a portable machine if practicable.

- 2 That it is highly desirable that one individual surgeon be responsible for the supervision of the care of fractures in each hospital service.
- 3 That special record sheets be used for fracture cases.
- 4 That a close follow up be maintained on all fracture cases for such time as necessary to establish an accurate knowledge of end results.

The personnel of the Committee on the Treatment of Fractures is as follows

Charles L. Scudder, Boston, *Chairman*
Frederic W. Bancroft, New York, *Secretary*

Wills C. Campbell,
Memphis
Idell Cohn,
New Orleans
H. Earle Conwell
Birmingham
Salvador Cordoba,
Venecuela
Frederic J. Cotton,
Boston
William R. Cuddihy,
Chicago
William Darrach,
New York

Frank D. Dickson,
Kansas City, Mo.
Eldridge L. Eliason,
Philadelphia
William L. Estes,
Bethlehem
W. Edward Galle,
Toronto
Fraser B. Gard, Montreal

Los Angeles
Philip D. Whelan, Boston

BOARD ON INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

FREDERIC A. RESLEY, M.D. WAUKEGAN, ILLINOIS, *Chairman*

THIS year we have to report that through the direction of Dr. Franklin H. Martin, the Director General the scope of the activities of this Board has been broadened and expanded in the field of medicine and surgery in industry. Dr. Williamson and Dr. Newquist have continued their contacts with large industrialists in their first hand fact finding surveys.

The following is a summary of Dr. Williamson's report.

SCOPE OF MEDICAL SERVICE

Only a small percentage of industries included in my survey extend medical treatment beyond the care of injuries and emergent and minor illness arising during working hours. Except for the hospitalization of major accidents and compensable cases requiring operating-room service and institutional care, the treatment of employees is generally restricted to that which can be rendered in the plant dispensary. It was found that 330 plants out of the 375 visited maintained a dispensary with facilities sufficient to supply the above service. The results of our studies show further that 221 (64.3 per cent) of the industries provide pre-employment physical examinations, while 115 (30.6 per cent) have periodic examinations of all or certain groups of workers, 200 companies (77.3 per cent) have some form of benefit plan in operation such as (1) mutual aid association maintained by the employees alone or on a contributory basis. The benefits are weekly cash allowances for a stated period payable for loss of time due to illness and non-compensable injuries. Only a small percentage of these associations provide the doctor's services. (2) Relief plan maintained by the company. (3) Group insurance plan which

provides benefits for total disability and death, and in a small number of cases an allowance is provided also for illness and non industrial injuries.

In conclusion, I would recommend that out of the 375 industries surveyed, 179 (45.8 per cent) be placed on the approved list that 153 (40.8 per cent) be not approved and that 43 (12 per cent) be conditionally approved pending the receipt of additional information.

Attention is again drawn to the fact that this report is confined to a survey of industries with 500 or more employees and the findings and the figures are not compared with medical conditions that exist in smaller industries.

The following is a summary of Dr. Newquist's report.

Since a Minimum Standard to insure adequate medical care has been adopted by the College it is the yard stick by which we measure such industrial medical service for subsequent rating or approval by the College.

Statistical data—

Number of Industries surveyed	246
Number of employees per industry ranged from 250 to 120,000—	
average	4,317
Total number of employees involved	1,062,000
Total number of employees having payroll deductions for complete medical and hospital service	
374,545 or 36 per cent	
Total number of employees having payroll deductions to include medical service for families	65,000 or 6 per cent

Types of compensation insurance—

	Total cases	Per cent
Self insured	16	51
Indemnity company	0	0
State compensation fund	50	20

Physicians—

Full time	101	41
Part time	56	34
On call	1	6
None designated	4	19

Dispensary facilities provided by industry

223 90

Pre-employment physical examinations in industry

14 0

Group insurance

10 69

Recommended for full approval by the College

135 55

Recommended for conditional approval by the College

1 6

Recommended for no approval by the College

94 39

We wish to emphasize the fact that the 36 per cent of employees in the industries we have surveyed who are served medically on a group insurance basis does not quite represent a true picture of the present situation in industry. We have not visited the

smaller industries where such conditions are not so prevalent. Further a complete and comprehensive survey has been made by Dr. Newquist of the Medical and Surgical situation in the state of West Virginia as it relates to the Workmen's Compensation Law and the State Institutions. This survey was requested and financed by the State Medical Society. His exhaustive report will be published in full.

On Friday afternoon, October 21, 1933 a meeting was held in St. Louis, the program being devoted to scientific discussion on medicine and surgery in industry.

The personnel of the Board on Industrial Medicine and Traumatic Surgery is as follows:

Frederic A. Besley, *Chairman*
Bowman C. Crowell, *Secretary*

John E. Bacon,	Thomas G. Orr
Miami, Arizona	Kansas City
Samuel R. Cunningham	W. O'Neill Sherman,
Oklahoma City	Pittsburgh
Donald Guthrie Sayre	Loyal A. Shoudy
Lucian H. Landry	Bethlehem
New Orleans	Ernst A. Sommer
A. D. Latenby, Baltimore	Portland
Charles F. Martin,	Frederick J. Tees,
Montreal	Montreal
Charles H. Mayo	John B. Walker
Rochester, Minn.	New York

REGISTRY OF BONE SARCOMA

BOWMAN C. CROWELL, M.D. CHICAGO Registrar

I HAVE the honor to submit the following report on the Registry of Bone Sarcoma.

During the year records of two hundred two cases of bone sarcoma have been submitted to the Registry and the most of these will be registered. In a few only is the information submitted to the Registry insufficient to justify registration. Five hundred eighty-one of the case records have been circulated and studied by thirty-four different individuals whose names appear on the classification sheets of the individual cases. Selected groups of cases have been issued upon request for educational purposes. The total number of cases in the Registry is now fourteen hundred four and they are classified as shown in accompanying table.

This year there have been eight additional cases of osteogenic sarcoma which have completed their 5 year survival period without recurrence of the tumor. Added to our previous figures this gives 59 in a total of 389 cases of osteogenic sarcoma living 5 years or more following treatment that is to say that the Committee unanimously agrees upon these 59 cases as being osteogenic sarcoma. There has been no meeting of the committee as a whole this year.

During the absence of the registrar on account of illness the scientific work of the registrar was carried on by Dr. Joseph J. Lebowitz and Dr. R. Bruce Malcolm to whom much credit is due for the manner in which they conducted the work. Detailed statistics are being prepared.

Osteogenic sarcoma	
Of the femur	289
Other than the femur	366
Ewing's sarcoma	156
Myeloma	53
Lymphosarcoma	6
Inflammation	69
Periosteal fibrosarcoma	24
Metastatic tumor	37
Angioma	9
Hemangio-endothelioma	10
Benign giant cell tumor	272
Giant cell tumor malignant	14
Benign osteogenic tumor	37
Unclassified and miscellaneous	16
Not bone tumors	

MEDICAL MOTION PICTURE FILMS

J. BENTLEY WINTER, M.D., New York, Chairman

THE importance of motion pictures as a means of disseminating medical knowledge has been generally accepted by the profession and there is an ever increasing interest in the subject. The American College of Surgeons is concerned with the Motion Picture Problem and has formed an American Film Film Committee to coordinate and coordinate as much as possible the production of the most effective medical films.

The Board on Medical Education of the American College of Surgeons has appointed the following members: Wm. H. Hays, Esq., New York, Chairman; J. Bender Smith, M.D., New York, Secretary; J. M. E. Trevelyan, M.D., Philadelphia, Secretary; V. W. Chalmers, M.D., New York, Secretary; H. A. Tamm, M.D., Chicago, Secretary; J. M. D. Cline, Esq., Chicago, Secretary; Charles H. Voss, M.D., Philadelphia, Secretary; C. Crowell, M.D., Chicago, Secretary; J. MacEachern, M.D., Chicago.

The College is very much interested in the production of medical motion pictures and has been successful in securing the cooperation of the motion picture industry in the production of films of medical interest. The College has a committee on motion pictures which is composed of representatives of the medical profession and the motion picture industry. This committee has been successful in securing the cooperation of the motion picture industry in the production of films of medical interest.

During the past few years my committee have been made in recording methods and in producing equipment that will be important factors in the production of talking films to the teaching of medicine in surgery. The Board on Medical Motion Picture Films is keenly interested in the development of the type of films and is maintaining close contact with the various organizations which are concerned with this phase of motion picture production and distribution of the films.

Very large audiences were present at all times in the continuous daily exhibition of medical motion pictures which was one of the features of the Clinical Congress of the College in St. Louis. The 35 films used for these demonstrations included several new talking films with both sound-on-film and disc recording.

Thirty-three reels of medical motion picture films have been approved by the American College of Surgeons and are available for distribution. Many additional films have been reviewed by the College, although they have not yet been formally approved. Our reviewing committees consider them to be an effective presentation of the subject matter and the procedures shown to be of interest and value.

Information pertaining to medical motion picture films may be obtained by communicating with the College.

THE LIBRARY AND DEPARTMENT OF LITERARY RESEARCH

THE Library of the College is the embodiment of the literary and scientific interests of the Fellows. The collection has grown steadily in the course of the past year through the addition of books and reprints written and presented by Fellows of the College. The reprints are supplied (preferably) in duplicate making possible the placing of one copy in the Fellow's file where it is a record of the work of that Fellow and the second in the classified package library section where it is available for circulation. In addition to the contributions from the Fellows, numerous friends of the College have presented copies of their works and from these sources the collection of current monographs has been augmented. Fellows and friends have likewise generously replied to the request for unbound journals and reprints and have notified the Library by letter or phone call when such material has been available so that it could be added to the collection already on file in the package library. Several members of the profession regularly keep in touch with the Library by this means.

Two collections are actively growing. The H. Winnett Orr collection of orthopedic works contains valuable historical material as well as later monographs and the Medical Women's Library, including books and pictures, is made up of interesting material.

The co-operation of the many Fellows who have contributed toward the development of the Library is greatly appreciated. It is hoped however that the number of those actively interested in building up this collection may be increased during the coming year. The Library is a phase of the College work in which each individual should have a part. It is his privilege to see that his work is represented to that collection as an inspiration to future generations of surgeons, and it is to his interest to aid to the enlargement of its resources by assisting in the transfer of any available collections (whether they be large or small and whether of current or historical interest). At the present time the oldest volume in the College Library is dated 1555. Any Fellow who has a book of earlier date or any old monograph for which he wishes to find a permanent home may find

a suitable place for it. In this collection College bookplates are available upon request. Those in charge of the Library will be glad to co-operate in making the collection thoroughly representative of the activities and interests of every Fellow of the College.

DEPARTMENT OF LITERARY RESEARCH

In conjunction with the Library, the Department of Literary Research has continued to render to Fellows of the College and members of the medical profession its three fold service including (1) package library material made up of reprints and clippings which are loaned free of charge (2) bibliographies compiled upon specific subjects at the request of the doctor and (3) abstracts and translations prepared in accordance with the instructions of the one submitting the request. During the past year, the Department has cared for the usual number of requests and the service has been even more prompt than in the past.

Taking into consideration the stringency of the times every effort has been made to keep the cost of each piece of work as low as is compatible with careful and accurate workmanship. Regardless of the present economic situation it must be recognized that translations to be of value must be carefully and accurately prepared. However in many cases the cost of the work can be reduced by the preparation of abstracts or summaries rather than complete translations and by the elimination of case reports and lengthy discussions of non-essential details. The familiarity of the College Research Staff with the medical literature in the various languages (German, French, Italian, Spanish, Swedish, Dutch and Russian) is an additional factor in the economical preparation of the translations. Thus by wise administration and careful management those directing the Department have been and are using every possible means of keeping the cost of research within the reach of every Fellow of the College so that practical considerations will not interrupt the flow of valuable contributions to scientific progress from this great body of men.

ST LOUIS COMMITTEE ON ARRANGEMENTS

Evaris A. Graham, *Chairman*, F. A. Jostes, *Secretary*, Fred Bailey, Willard Bartlett, M. B. Clopton, William T. Coughlin, Clarence H. Crego Jr., L. W. Dean, Ellis Fischel, W. C. Gibson, William P. Glennon, Max Goldstein, John Green, H. A. Hanser, Roland Hill, Harvey J. Howard, Charles E. Hyndman, Walter Jones, R. Emmet Kane, W. C. G. Kurchner, W. E. Leighton, Curtis H. Lohr, William H. Luedde, Melvin Marriott, Harvey S. McKay, H. G. Mudd, James Mudd, Max Miver, Louis Ransieur, Francis Rader, William E. Sauer, Otto Schwarz, Alphonse M. Schwittalla, Major Seelig, Omar R. Sevin, Carroll Smith, Max Starkloff, Ross Woolker, O. B. Ziemert

SUB-COMMITTEES

Ophthalmology and Otorhinology
L. W. Dean, *Chairman*, Max Goldstein, John Green, Harvey J. Howard, William H. Luedde, William E. Saver

Community Health Meeting

Ellis Fischel, *Chairman*, Fred Bailey, Charles E. Hyndman, F. A. Jostes, Francis Rader, John Sotter.

Paediatric

Major Seelig, *Chairman*

OFFICERS ELECTED

President, William D. Haggard, Nashville.
Vice-Presidents, Evaris A. Graham, St. Louis, Alexander R. Munroe, Edmonton.

Reigns for term expiring in 1935: Irvin Abell, Louisville; John R. Fraser, Montreal; Franklin H. Martin, Chicago; George P. Moller, Philadelphia; Richard R. Smith, Grand Rapids.

Members of the Board of Governors for term expiring in 1935: Fred H. Albee, New York; Edward W. Archibald, Montreal; Samuel C. Baldwin, Salt Lake City; Joseph C. Beck, Chicago; Frederic A. Beale, Waukegan, Illinois; William V. Bisham, Washington; Joseph C. Bloodgood, Baltimore; Frank K. Boland, Atlanta; Frank E. Burch, St. Paul; Henry T. Byford, Chicago; Walter W. Chipman, Montreal; Frederic J. Cotton, Boston; William L. Cousins, Portland; Maine; A. J. Crowell, Charlotte; Thomas S. Cullen, Baltimore; Carl Henry Davis, Milwaukee; Edward P. Davis, Philadelphia; Lee Wallace Dean, St. Louis; Edward C. Ellett,

Memphis; George Gellhorn, St. Louis; Oliver D. Hamlin, Oakland; Casper F. Hegner, Denver; George J. Heuer, New York; Gerry R. Holden, Jacksonville; Edward J. Ill, Newark; Jabez N. Jackson, Kansas City; Missouri; John E. Jennings, Brooklyn; Burton J. Lee, New York; Southgate Leigh, Norfolk; Jennings C. Litzberg, Minneapolis; John Prentiss Lord, Omaha; William H. Luedde, St. Louis; John G. MacDougall, Halifax; William B. Owen, Louisville; Robert Lee Payne, Norfolk; Harold E. Ridewood, Victoria, B. C.; Hubert A. Royner, Raleigh; Arthur M. Shipley, Baltimore; Wells Ferrin Smith, Little Rock; George V. J. Sommer, Trenton; Frederic V. G. Starr, Toronto; Julia C. Strawn, Chicago; George W. Swift, Seattle; Howard C. Taylor, New York; Wallace I. Terry, San Francisco; Clarence G. Tuland, Los Angeles; Edgar A. Vander Veer, Albany; John B. Walker, New York; George Gray Ward, New York; Horace J. Whitacre, Tacoma.

HOSPITAL STANDARDIZATION

REPORT OF 1932 CONFERENCE IN ST LOUIS

An abstract of the papers and discussions presented at the Hospital Standardization Conference held during the Clinical Congress of the American College of Surgeons at St. Louis October 17-21, 1932 is presented in the following pages. Allen B. Kanavel, M.D., Chicago, past-president of the College, presided.

GREETINGS

Greetings were given by the president-elect, J. BENTLEY SOUTER, M.D., New York, who referred briefly to the Hospital Standardization movement and its accomplishments during the past 15 years.

OPENING ADDRESS

An appropriate address of welcome was made by CURTIS H. LOHR, M.D., St. Louis, in which he referred to the progress made in hospital service generally, mentioning particularly the substantial contribution of the American College of Surgeons through its hospital standardization movement. He announced that five of the city institutions under his jurisdiction were included this year in the list of approved hospitals published by the American College of Surgeons. In making the announcement, he said it would always be his purpose as hospital commissioner to keep all city institutions meeting the high standards. In reference to political tax-supported institutions, he was of the opinion that such conditions could be avoided if there existed between hospital managements and commissioners the understanding that service to the patient must always be the primary consideration. He appealed to those superintendents of tax-supported hospitals who would stick firmly to their convictions and carry out the best principles of Hospital Standardization regardless of political interference.

PRESENTATION OF THE FIFTEENTH ANNUAL REPORT OF HOSPITAL STANDARDIZATION

FRANKLIN H. MARTIN, M.D., Chicago, speaking in behalf of the American College of Surgeons of which this Hospital Conference is the guest, may I, before presenting the annual report of our approved hospitals, say a few words regarding one or more acute problems.

The college has found no more dependable protection against fee-splitting than the influence of the staffs and superintendents of our approved hospitals. We must guard ourselves against the subtle commercialism of some of our own confrères. Every

hospital must safeguard its medical staff and the general practitioners by refusing to permit irregulars to practice in the institution. In dealing with a hospital that fails to protect the scientific profession against such invasion, the College has no alternative—it must remove the hospital from the approved list.

Hospitals and the medical profession are being embarrassed by the construction of many institutions by the government to care for disabled veterans of all wars. New hospitals are being built in face of the fact that there are several thousand general and community hospitals with well organized staffs in which these soldier patients could be properly cared for in their respective communities by their own doctors and at much less expense to the government than by the present program which involves huge expenditures.

Furthermore, it is alleged that from two-thirds to three-fourths of the patients in Veterans Administration hospitals are comprised of veterans suffering from diseases and disabilities in no way traceable to war service. In order to check this menace we must act promptly. Letters and telegrams of protest should be sent at once to those who are responsible for this government ownership of our activities and to those who are in a position to remedy it.

In order to minimize the cost of hospitalization several points of conduct should be watched: (a) extravagance in building, (b) inefficiency of service, (c) carelessness in segregating patients according to their ability to pay, (d) lack of provision for moderate priced rooms, (e) disproportionate laboratory, X-ray, and other diagnostic accessories, and possible overcharge, (f) lack of discrimination in applying extras in accordance with individual needs, (g) indiscriminate supplying of food, (h) extravagant assignment of nurses, (i) excessive charges for operating room anesthetics, etc.

For 4 years the Hospital Department of the College has urged our approved hospitals to co-operate with the independent practitioners of medicine by offering the services of their institutions for diagnostic purposes through the establishing of health inventonums. Through furnishing its facilities for the thorough periodic health examinations of individuals by their own physicians, the hospital would become the meeting ground for all regular practitioners, and the haven of the community. It would solve the problems of all physicians and their patients in the conduct of diag-

poetic service, and would insure to the hospital a friendly clientele of transcendent importance. It would aid in the establishment of tumor and cancer clinics, and emphasize also the importance of establishing special services for the early diagnosis of other preventable diseases.

Following is a summary of the results of the 1932 Hospital Standardization survey

Hospitals of 20 beds and over	
Surveyed	575
Fully approved	418
Percentage fully approved	60.6
Conditionally approved	57
Percentage conditionally approved	3.3
Not approved	0

Hospitals 100 beds and over	93.9
Hospitals 50 beds and over	81.4
Hospitals 25 beds and over	67.3

THE STANDARDIZED HOSPITAL AS A MEDICAL EDUCATIONAL CENTER

ALLEN B. KANAVEL, M.D., Chicago. The standardized hospital offers the best means of providing a continued education for physicians and is a fertile source of information for the public. So that it may function most efficiently as a teaching center it is necessary however that there be a broader conception of the functions of the standardized hospital. The staffs of these institutions, both physicians and nurses, must divest their minds of the idea that they are founded solely to furnish medical service to the patient coming to their doors. The community hospital as well as the university hospital must become a teaching center.

In their plans for furthering the education of physicians the staffs of the standardized hospital should so organize their activities as to give systematic instruction to their internes, establish residencies for aspiring specialists, and provide adequate opportunities for the education of the general practitioner in the later developments of medicine. Instead of the *laissez faire* attitude toward interne instruction now so common in hospitals, the interne should be encouraged by organized effort to pursue the systematic reading of good medical literature, to carry on the intensive study of group cases, and to make reports of his clinical investigations to the assembled staff where free discussion by internes, residents, and the staff will clarify his knowledge. Periodic pathological conferences will arouse his interest and be of value to the whole medical group.

Every hospital should aspire to the establishing of residencies of 1, 2, or 3 years according to its size and opportunities. These residents may come from the interne body but it is to be hoped that here the physician who has been out in general practice may find the opportunity for perfecting himself in some special line. These aspiring specialists should be assigned to those particularly qualified to guide them in their reading and practice. They should be encouraged to carry on experimental and clinical studies, a by-product of which would be medical articles for publication but the greatest value would come to the resident through the development of his habits of observation, perfection of his critical analysis of disease, and particularly of his imagination.

The standardized hospital should be the center for the dissemination of new procedures and new knowledge to the practicing physician. We have all recognized our need of continued instruction and attempted to meet it by attending medical meetings and post graduate clinical weeks. The inadequacy of didactic teaching of this type is too well known to deserve comment. Of much more value would be instructional courses given in the standardized hospitals by qualified members of the profession not lectures but systematic laboratory courses and actual demonstrations of pathological material, chemical procedures, the treatment of emergencies, the recognition of uncommon conditions, and the treatment of the simpler diseased conditions coming within the realm of the specialist. So far as possible such courses should consist of actual work by the practitioner and be limited to a few participants.

Of equal importance is the systematic instruction of the community in the knowledge of the principles of scientific medicine. Addresses to the community upon practical subjects by the local profession under the auspices of the hospitals and sponsored by civic organizations such as churches, lodges, business men's organizations, women's clubs, etc. will arouse general interest. Such instruction might well include special group classes in domestic science, the preparation of diet in health and disease, simple nursing aids, care of expectant mothers, care of babies and the preparation of their foods, lectures upon contagious diseases, the recognition of emergencies, sexual hygiene, and marital relationships.

The hospital should foster the health inventiveness by providing facilities for the profession to carry on this work in a systematic manner at a nominal expense. Such public instruction will not only be of value to our people but will also attach to the hospitals the loyal support of our citizens and diminish the menace of quackery.

DISCUSSION

HORACE J. WHITACRE, M.D., Tacoma, Washington. Undoubtedly, adult education, or a continuation of education after the intensive study of college days, is one of the real problems of society, whether this education concerns general problems or specialized fields. There is perhaps no social group that has done a better job of continuation study than the medical profession, as it is carried on through county, state, national, and specialized society meetings where advances in scientific medicine are discussed and general information advanced. The hospital of each community provides a very practical agency, however, which is not covered by any of the activities mentioned and has great potentialities for the increase of practical directly usable knowledge among physicians.

There need not be any conflict between the educational program of the hospital staff and that of the county medical society. The county medical society is the legitimate place for formal papers and organization work, while the program of the hospital

staff meeting is confined strictly to the presentation of specific cases in the hospital, demonstration of diagnostic methods, laboratory technique and autopsy findings.

The most important place for the development of a well organized educational program within a hospital is the community where there is no teaching institution. I represent such a community. We feel that the most important element in our hospital educational organization is a full time pathologist who has definite teaching ability. We hold regular monthly staff meetings, a weekly medical clinic, a weekly tumor clinic, regular meetings of an interne and an ex-interne group, and a continuously operating anatomical dissection department. In all of these our full time pathologist is in a large measure the leader and to a considerable extent the hub of the wheel.

This arrangement prevents us from degenerating to the unprofitable routine of reporting successful cases and maintains a status of scientific alertness.

THE CHANGING RELATIONSHIP OF THE DOCTOR TO HIS WORKSHOP

C. HARLEY AGNEW, M.D., Toronto. The influence of the hospital on the practice of medicine while evolutionary has been actually revolutionary. A few decades ago the average doctor was very little interested in the hospital. The majority of patients were treated at home. Only as a last resort would a patient consent to go to a hospital of which there were very few outside of large cities and those were comparatively closed to a small staff.

Now the picture is changed. There is a vast chain of hospitals everywhere. More and more medical work is being transferred to the hospital so that the doctor must ally himself more closely with his workshop today than he did in the past. The medical profession is realizing its responsibility and obligations to the hospital and staff appointments are now properly appreciated. An increased interest is being manifested in staff meetings with more co-operation and *esprit de corps*. Particularly gratifying is the greater co-operation between medical staff and the administration groups in hospital work.

What of the future? Hospitalization cannot but increase thereby making it more essential than ever before that every doctor have access to some hospital. The effort to lessen the cost of diagnosis will probably result in greater utilization of hospital facilities by doctors whose co-operative practices may be grouped about the hospital itself. Should health insurance ever come, the experience of other countries would indicate that the relationship of a large portion of the profession may undergo considerable change.

The increasing utilization of public ward services by industrial and social organizations for the hospitalization of patients on a benefit or co-operative scheme, many of whom could afford to pay for a physician, is victimizing the profession to an intolerable degree. In a Report of the joint committee

of the British Medical Association and the British Hospitals Association in Great Britain there is shown a definite preference for the payment of the visiting staffs.

It is becoming increasingly apparent that the physician's activities and interests, his future, his very life are indissolubly bound up with the hospital. No more can he hold aloof from the hospital, scorn the multitudinous staff responsibilities, or maintain his professional prestige without that very stimulating and chastening contact with his colleagues in ward and theater.

And with the realization of this partnership has arisen a new sense of responsibility of obligation toward the hospital. The more this duty is realized, the more is a staff appointment appreciated—not as a divine right but as a privilege, as an opportunity for professional improvement, for scientific stimulation, and for greater service to the sick poor.

Discussion

WILLIAM D. CUTLER, M.D. Chicago. A recent analysis shows that in the United States more than 50 per cent of the practicing physicians have hospital connections. The doctors themselves have been most active in increasing the number of institutions and in devoting a larger proportion of their own time to practice within hospitals. Obviously by so doing the physician saves a great deal of time and energy otherwise consumed in visiting his patients in their homes. In hospital practice the doctor saves money for it relieves him of the necessity of providing in his office such expensive equipment as operating rooms, laboratories, and X-ray machines for diagnosis and treatment.

In the hospital the physician has at his command trained assistants, internes, nurses, and technicians who will carry out his orders, supervise treatment, and in diagnosis, and, in general, greatly increase his effectiveness in caring for the patient.

Another substantial advantage which comes to the physician practicing in the hospital is derived from the opportunities for contact with his professional colleagues. Casual meetings and formal consultations enable him to keep better informed as to what others are doing in his own and related fields.

The present regimen has proved itself of greatest advantage to the patients who save time otherwise consumed in going back and forth to the doctors' offices. Moreover it is an indisputable fact that better care can be obtained in the hospital than in the home.

Slowly but surely the doctors are transferring their care of ambulatory patients to offices which now are provided in many institutions, resulting in the numerous advantages already cited. Even the hospital finds it advantageous for the physician to carry on his private practice within its walls for it makes him more readily available at all hours of the day.

In connection with problems of health insurance, some hospitals have already undertaken to supply

their communities with medical service at a fixed rate. Inasmuch as these arrangements sometimes include medical as well as hospital care, it is clear that our profession is vitally concerned to see that such arrangements are based upon due regard for the physicians' rights—otherwise, the hospital, or insurance company may assume the right to sell the doctor's services without giving him a voice in determining the conditions under which he will render those services.

Surgeons more than any other group of physicians, are dependent upon hospital facilities and, at the same time, they furnish a larger quota of patients. Therefore, it is to them that we may justly look for leadership in adjusting the relationship of our profession to the community through the hospital, in such manner as to safeguard the vital interests which we have at stake.

MEDICAL AND HOSPITAL ECONOMICS

FREDERIC A. BENLEY, M.D. Waukegan, Illinois. The Hon. Newton D. Baker has said recently that "America will be on trial this winter" and we might paraphrase this to state that the American hospital system will be on trial this winter. The solution and the answer to all the problems involved in the situation cannot be prophesied accurately.

The mounting and ever increasing cost of the maintenance of hospitals has been a problem that has confronted all hospital managements during the past decade and has required the continued and correlated efforts of the best financial minds to cope with these changing conditions which are rapidly becoming more acute. Hospitals have been compelled to increase their budgets because of the cost of elaborately equipped X-ray departments and complete scientific laboratories, with their accompanying staffs of high salaried technicians. The supplanting of the 3 year course for nurses instead of 2 years of training, and the demands of physicians and surgeons for more scientific care for their patients in hospitals have meant an increasing financial budget.

It is an evident fact that the average patient cannot afford to pay for the high quality of service which he needs and to which he is rightfully entitled. Some arrangement must be evolved whereby this enormous financial burden can be distributed and paid collectively. Perhaps the costs of hospitalization of many patients could be assumed by some collective agency such as insurance.

It is not exactly accurate to say that communities are overhospitalized. True, there are many unoccupied beds throughout the country. But it is just as true that there are as many and more patients requiring hospitalization who have not the financial resources to avail themselves of these unoccupied beds.

If the Veterans Administration hospitals would restrict their services to diseases and injuries contracted in the line of duty and to dependents of those who made the supreme sacrifice, then many of the

now unoccupied beds in other hospitals would be come occupied.

HOW THE HOSPITAL MANAGEMENT AND MEDICAL STAFF CAN CO-OPERATE IN REDUCING THE MORTALITY OF APPENDICITIS

JOHN O BOWER M D Philadelphia Approx imately 20 000 die annually in the United States from appendicitis and the complications associated with it The death rate of 183 American cities with an aggregate population of 43 000 000 in 1931 was 17 9 per 100 000 The increase in mortality from 1910 to 1931 in 60 cities in the United States with an aggregate population of more than 28 000 000 was 31 5 per cent The death rate per 100 000 in these was 17 4 In 64 foreign cities of corresponding importance with an aggregate population of more than 56 000 000 in 1931 the death rate was 8 0 per 100 000 Why is the death rate in the United States 124 per cent greater than in Europe? Our medical and surgical abilities are certainly equal and our hospital facilities just as good.

Pre-hospital factors are responsible This accounts for the futility of the efforts of physicians and surgeons to reduce the mortality The responsibility for the outcome of the patient who enters the hospital with acute appendicitis is the surgeon's Yet in 90 per cent of the deaths the advice of family friends, druggist and family physician has contributed more to the fatal outcome than the surgeon's management.

Any plan to combat the increasing mortality of acute appendicitis must include a program of publicity The problem of the increase is not the surgeon's primarily it must be met by the co-ordinated efforts of a national organization such as the American College of Surgeons the departments of health of every city and by the medical staff and management of all hospitals The success of the plan for the reduction of mortality of acute appendicitis as it pertains to the individual hospital depends upon co-operation between staff and management.

The member of the staff chosen by the chief of staff and the medical director or superintendent should preferably be a surgeon but if he is vitally interested in the campaign, experienced in clinical research and willing to supervise the details incident to statistical studies, he should be chosen without regard to rank or preference.

For a successful plan of publicity there must be (1) an analysis of all clinical records of acute appendicitis both private and ward of the previous 2 years (2) presentation of results of analysis to the medical staff and those physicians sending patients to the hospital (3) a letter with explanatory detail enclosed (in the form of a sticker warning) mailed to above mentioned physicians (4) surveys made and letters noting any progress together with stickers sent out at varying intervals of from 3 to 6 months (5) a complete survey made at end of current year with results.

As soon as the survey is completed the results must be presented to the staff, outside physicians and the public Sticker warnings sent to the family physician who in turn sends them to his clientele will be particularly effective However one of the greatest aids is the frank discussion of the hospital mortality it must be talked about it must be visualized it must be brought into the open

OXYGEN THERAPY IN HOSPITALS, EQUIPMENT AND MANAGEMENT OF SERVICE

WILLIAM THALIMIER M D Chicago Anoxemia is the one fundamental indication for treatment with oxygen The only accurate method for determining the degree of anoxemia is actually to determine the amount of oxygen present in the arterial blood The use of oxygen therapy in our hospital has increased until now we are trying to anticipate the development of anoxemia and prevent it or if we cannot do this at least to use oxygen at the earliest indication of anoxemia.

The advantages of the oxygen room are accurate and constant control of percentage of oxygen conditioning of the temperature, and humidity of the atmosphere, ability to give the patient complete nursing and medical care as in any other room relieving the patient of the sense of confinement as in an oxygen tent The disadvantages of the oxygen room are mainly that it is more expensive to erect than more oxygen, and requires a special nursing force

The advantages of oxygen tents are mobility, that is one can bring the tent to the patient's bed, they are less expensive than oxygen rooms, and require less oxygen The disadvantages are that some patients are badly affected by the feeling of confinement in the tent, very restless patients are difficult to control, and delirious patients impossible to control It is difficult to maintain a 50 per cent oxygen content because of having to open the tent to feed and care for the patient It is more difficult to give nursing care more difficult to control the temperature oxygen tents require constant supervision by someone with the proper technical training.

The nasal catheter method has the advantages of simplicity and economy The main disadvantages might arise from discomfort caused to the patient limitations when the patient is restless or delirious and the necessity of care on insertion of the catheter by a physician and constant supervision by him There is the danger that if the catheter is inserted too far into the pharynx, that the patient may be forced to swallow the oxygen mixed with air or the stomach may even become distended with this atmosphere.

It is imperative that one member of the clinical staff be interested in oxygen therapy from both the therapeutic and research points of view He can train a technician, nurse, or interne in all of the essentials, he can stimulate the rest of the staff to maintain an open mind as to the value and usefulness

of oxygen therapy. He will find many fields still open for research and many opportunities for careful scientific observations.

For the proper care and installation of oxygen tents, for the use of an oxygen room, to be certain that 50 per cent oxygen is being maintained, and that equipment is not being neglected or damaged it is absolutely necessary to have the services of an able technician.

It is my hope that it will be possible to reduce the cost of oxygen therapy service in hospitals and in homes so that oxygen treatment can be given a larger trial earlier in the course of various diseases, and so that many more observations can be made to determine the extent of usefulness in what I consider a very valuable therapeutic aid.

DISCUSSION

LEONARD W. CRILE, M.D. Cleveland, Ohio. It is the custom at the Cleveland Clinic to deal with depression and shock prophylactically. Since the basis of energy is oxidation it is through oxidation that the electrical potential of the cells is built up and maintained, and therefore it is through oxidation that the normal activity of all the organs and tissues of the body is maintained. In depression and shock there is a failure of the actual oxidation in the body that is to say a failure of the internal respiration of the body corresponding to the degree of the depression and shock. If in the course of a surgical operation the patient is depressed by surgical shock or by hemorrhage or by infection, or by crises of hyperthyroidism, it means that countless millions of organic molecules have broken down and these can be restored and repaired only by rest, sleep and normal oxidation.

We treat our patients on a statistical basis, that is, our indications for preventive treatment are based upon the statistical evidence, not the clinical evidence in each group of patients. If we are proposing to perform an operation upon the common duct in a jaundiced and sick patient, if we are resecting the large intestine for carcinoma if there is an emaciated patient with hyperthyroidism or a case of hyperthyroidism in which emaciation, myocardial decompensation, nephritis, etc. are present, if a resection of the stomach is to be done if for any reason the risk is poor then regardless of the cause, in all these cases we give a blood transfusion in advance of operation, intravenous injections of glucose, injections of normal saline and urge water by mouth or give it by hypodermoclysis—thus the electrolytic balance is built up before the operation, and then during the operation we maintain the body temperature in certain of these cases by diathermy.

We use local, regional, or spinal anesthesia together with a small amount of nitrous oxide oxygen; we avoid deep, general anesthesia which interferes with the internal respiration, that is, the oxidation, which means that the anesthesia itself is doing the same thing to the patient as the surgical operation. When we have finished an operation per-

formed under the above listed conditions, the patient's condition may seem to have been very little disturbed by the operation but we know from statistical experience that that patient is still in the bad risk class. We, therefore, put the patient immediately into an oxygen tent and give him infusions of saline solution and we protect him against pain. We continue the protection of his body temperature by applying diathermy if there is any fall below the normal.

One of the most important measures of all is the immediate use of oxygen, that is, putting the patient into an oxygen tent. By doing this we have to an extraordinary degree cut down the mortality rates in these various bad risk patients. For instance, we now have a series of 1,473 operations for hyperthyroidism in patients under 45 years of age without a death. We have seen the mortality rate fall in the whole group of bad risk operations.

Not only does this general plan of maintaining a high level of resistance in the patient prevent the breakdown of the myocardium, of the kidney, the liver, the pancreas, and the brain, but it sets up the best type of defense against infection, pneumonia and wound infection. In other words, we have set up a formula for raising and maintaining the vitality of the patient before, during, and after the operation and one of the essential factors in this formula is the oxygen tent.

PERSISTENT PROBLEMS AFFECTING HOSPITALS AND THEIR SOLUTION—FROM A NATION-WIDE SURVEY

E. MURIEL ANSCOMBE, R.N. St. Louis. Several factors are contributing to the lowered occupancy of our hospitals. Non-tax supported hospitals are doing more than their share of free work, but are being deprived of the patronage of patients who can afford to pay, by the admittance of private patients to city hospitals. Some plan should be evolved whereby private patients are entirely excluded from public institutions, and non-tax-supported hospitals given financial aid for each charity patient treated.

Group insurance may be a partial solution of the hospital's financial problem. It should, however, provide protection for the individual and prove satisfactory to the physicians.

Articles and editorials which have appeared recently in different professional magazines indicate the need of a specific preparation for the hospital administrative field. Should not some provision be made for an educational program and registration of hospital superintendents that will make it incumbent upon hospitals to employ a properly prepared superintendent if they wish to obtain institutional membership in the American Hospital Association and become approved by the American College of Surgeons?

Boards of Trustees would be taking a step in the right direction by appointing to their staffs only those physicians who have no other hospital

affiliations. This would stimulate a sense of ownership and personal responsibility in institutions. With their patients concentrated in one hospital physicians could devote more time to planning and carrying out an intensive teaching program. They could give closer supervision to the patient's history and have more time for research work.

Without careful supervision and follow up work internes will not get the best which the hospital has to offer. Hospital administrators should feel their responsibility in the development of the interne. The largest hospital does not always furnish the best training; it depends largely upon the organization, the research spirit which prevails and the interest of the staff members in the interne group.

Hospitals are being criticized today for turning out too many nurses. The adoption of uniform standards by a national board or commission working in conjunction with the National League of Nursing Education would automatically eliminate many schools and just as definitely result in a marked decrease in the number of students who are admitted to our schools.

Discussion

W. HAMILTON CRAWFORD, Hattiesburg, Missis. suppl. For several years it has been my conviction that field secretaries should be established at geographical points by the American Hospital Association so that a more intimate relationship might be developed between the members and the association.

The pivot man in any hospital is of course the superintendent. How may we be expected to convince a public that certain recognition should be extended hospitals when staring so many communities in the face is an exhibit of incompetency bearing the title of superintendent?

Several superintendents today are uncertain of the permanence of their positions because of competition of members of their boards seeking to supersede them. We may expect this situation to continue until an intelligent standard is set up for extending recognition to those qualified.

Why not create the American College of Hospital Superintendents to stand out as a separate and distinct ethical and influential college presenting fellowships only where requirements have been fully met?

A plan of public relations as outlined by the Committee of the American Hospital Association would undoubtedly create the proper perspective between hospitals and society.

A three fold program to solve pertinent problems affecting hospitals should include it seems to me the following:

1. Program of public relations.
2. American Hospital Association program as advocated by Plan and Scope Committee.
3. Establishment of the American College of Hospital Superintendents.

ECONOMIC CONDITIONS AS THEY AFFECT CANADIAN HOSPITALS AND HOW THEY ARE BEING MET

ARTHUR J. SWANSON, Toronto. The hospitals of both Canada and the United States are having a difficult time and are frantically searching for new means of increasing revenue. We in Canada have endeavored to gain some measure of relief through five major means.

1. *By reducing expenditures.* In addition to the reduced prices of commodities many savings can be made through using more up-to-date equipment, through rearranging the duties of the staff so as to allow more evenly distributed employment and through the rearrangement of hospital clinics so that space is kept busier.

2. *By selling hospital service to the community.* By setting out deliberately to give the utmost in service to the public and your staff doctors a considerable amount of business can be salvaged at this time. To my mind it is good service that is going to be the deciding factor as to whether the hospitals will be kept busy.

3. *By making the state assume its responsibility to indigent and part pay patients.* In Ontario the Government sets the rate which may be charged public ward patients at \$1.75 per day and 90 cents for infants born in the hospital; this amount to be paid by the patient or if that is impossible by the municipality sending in the patient. In addition to this \$1.75 per day the Government of the Province pays 60 cents per day for every patient in the public wards and 30 cents per day for every infant born in the institution. It is admitted that this rate does not by any means cover the cost of maintaining the patients even in the lowest priced accommodations but the hospital receives a definite amount for patients who otherwise would be treated free. In other provinces the rate varies. When it became evident in Ontario that the government intended to reduce the grant a large deputation of the provincial hospital association met the Prime Minister and some of the Cabinet members and succeeded in maintaining the grant rate. This indicates what a well organized hospital association can do to keep the needs of the hospitals before the Government and the public at all times.

4. *By relief from taxation and other duties.* Thousands of dollars are saved annually for Canadian hospitals because most articles of hospital equipment are exempt from duty. Moreover the hospitals are exempt from the payment of sales tax on everything purchased for hospital use even including material used for additions to existing buildings. The exemptions were made through the efforts of our various hospital associations and our very energetic director of Hospital Service for the Canadian Medical Association.

5. *By a contributory system.* This system may be called "hospital insurance" or "advanced payment system." Call it what you will this is something which must be seriously considered by all hospital

administrators before long. Some of our hospitals have found this system a very satisfactory way of insuring revenue. Prepayment certificates are being issued whereby potential patients buy in advance certificates entitling them to a definite value in hospital service. By means of these certificates payment for hospitalization is spread over a considerable period before, during, and after the actual period of hospitalization.

OBLIGATIONS OF GENERAL HOSPITALS IN PROVIDING BETTER SERVICE FOR THE CANCER PATIENT

BURTON J. LEE, M.D., New York. The American College of Surgeons in co-operation with the American Society for the Control of Cancer has been engaged for some years in the organization of cancer clinics in this country and in Canada. Although splendid cancer institutes exist in some of the larger centers, the bulk of the vast numbers of patients suffering with cancer inevitably find their way to large general hospitals where adequate service should be provided. These institutions must realize the obligation which rests upon them in connection with this major health problem.

To meet this need cancer clinics with satisfactory surgical and radiological equipment and well trained staffs are being organized all over America. Indeed, no large general hospital can be considered a complete institution today unless a well organized cancer service exists within its doors. It must be borne in mind, furthermore, that cancer itself is a distinct field apart from general medicine and surgery.

A cancer clinic to be complete must incorporate the new science of radiology with the co-operation of an intelligent and interested radiologist who has at his hand modern radiological equipment for diagnosis and treatment. An adequate supply of radium is necessary but more important is a group of men trained to use this agent intelligently. The technique of radium therapy is a science and an art in itself but it cannot be separated from proper surgical technique inasmuch as many special surgical procedures must be carried out in connection with radium therapy. A pathologist interested in neoplastic diseases is one of the key men in the personnel of a cancer clinic. But the care of a cancer patient can never be assigned to a single individual. Group judgment is necessary if the patient is to receive the best in diagnosis and treatment.

DISCUSSION

HOWMAN C. CROWELL, M.D., Chicago. The success of the hospital today can be measured only by the condition of its patients after they have left its doors. Yet the future of the discharged patient is in most instances entirely unknown to hospitals. He might well be called the forgotten patient.

Follow-up are important not only to gauge the efficiency of the hospital's staff, but to make sure that the treatment given the patient will be of more than temporary duration.

Hospitals must induce their patients to return for re-examinations. If they desire to make their services of real and lasting benefit, they must install new record systems with a workable plan for definite follow-ups.

FOLLOW-UP AND STUDY OF END-RESULTS AS CARRIED ON BY THE MAYO CLINIC

ALFRED W. ADSON, M.D., Rochester. The taking of careful histories and the recording of physical and laboratory reports are essential to the diagnosis of a patient. But the treatment of future patients with similar ailments depends upon the results accomplished by the medical or surgical treatment instituted. It is true that one may be capable of remembering the results obtained in some particular case or in a small group of cases, but in order to make a thorough analysis of a large series of cases, much depends upon the follow-up study.

In some departments of the Clinic, follow-up data are obtained by personal letters to family physicians or to the patients themselves. In other departments circular letters pertaining to the specific disease are mailed at regular intervals or at times when special investigation is being made. These data are often supplemented by photographs, roentgenograms, laboratory ophthalmological, neurological, and physical examinations while others who have failed to get the desired results are encouraged to return for re-examination, which affords evidence for the more accurate follow-up study. Letters from patients are not always reliable, as the results may be colored by the amount of the outstanding account or the disability insurance they are receiving. The report of the family physician is the most valuable follow-up system.

Once all these data are acquired, it is essential to record them either on the history or charts, or on cards for mechanical tabulation which permits comparison of pretherapeutic findings in order to evaluate results accomplished. Therefore, it is obvious in comparing the results obtained by the various therapeutic measures that one readily learns which treatment is valuable, and by expounding our facts further thought is stimulated to arrive at the correct diagnosis and the best treatment to employ.

FIXING THE TRIPLE VIEWPOINTS ON NURSING—DOCTORS, NURSES AND HOSPITAL EXECUTIVES

MARY M. ROBERTS, R.N., New York. Our system of nursing education has been surprisingly good, but it is now outworn. We need a new system to free the hospitals, which are service organizations, of the economic responsibility for educational institutions. The most vital part of a nurse's training must always be secured where the patients are—in the hospital—but by what use of existing educational institutions for science courses and other academic work, the change can be brought about. A good deal depends upon the hospitals' willingness to so organize their nursing services that there shall be

at least a skeleton organization of graduate service a service apart from the numbers of graduates needed for supervision. Into well organized services we shall be able to project students for training in the expectation that they will constantly see and therefore practice good nursing—an outcome deeply desired for patients by doctors and nurses alike.

Today we have many more nurses than we need to meet effective demands, and much of the over production is of poorly prepared nurses. In a study of the nursing services of sixteen middle western hospitals, the American Nurses Association recently discovered that only 33 per cent of the applicants were eligible for staff nursing.

Doctors know extraordinarily little about nursing. With their willingness to help, and with the co-operation of nurses and hospital executives together with the aid of the public, nurses can be better prepared. It is upon the public that the responsibility for the education of public servants should rest.

Hospital nursing service and school of nursing should never be thought of as synonymous terms even when the school contributes richly to the service and the service to the school. The hospital is responsible for its own nursing service. It should be freed from the economic and educational burden of a school.

School of nursing must be made to mean a place in which young women are prepared for service as *graduate nurses* in what may be called first level positions. This implies a sufficient body of basic sciences to provide a background for a rounded clinical preparation including mental and communicable disease nursing and the principles of public health. Further preparation than that should be secured through postgraduate courses.

Discussion

DONALD GUTHRIE, M.D., Sayre, Pennsylvania. I do not believe that the medical profession criticizes nursing for a lack of training or practice. Most of the criticism is brought forth because of the nurse's inability to adapt herself to her patient and to her own surroundings.

Psychology has been wisely added to the curriculum but as a science it is difficult for the average pupil to understand. Would it not be better to teach psychology in a more practical way and to bend our efforts toward developing the personalities of our students? I am satisfied that if our nurses could be skillfully trained in practical psychology there would be much less criticism of their work by the public and by the medical profession. The art in nursing and in medicine must never be replaced by pure science, for if it is, it will be unfortunate for both professions.

BASIC STANDARDS FOR SCHOOLS OF NURSING

REV ALPHONSE M. SCHWITALA, S.J. Ph.D. St. Louis. In advocating any set of basic standards for schools of nursing, the first principle to be recognized by the school is the educational level from which its students are derived. Essentially the school of nursing is a professional college. That does not mean that schools of nursing should blindly and uncritically take over the whole sum and substance of college administration, but the school's attitude toward a student should be that of the solid college of arts and sciences.

The school of nursing must understand the life for which it is preparing the student nurse. Because of the constantly increasing stress and complexity of our world the school must differentiate between cultural courses, basic sciences, medical courses, and nursing courses in the curriculum. If the school of nursing is of collegiate rank, then surely it must impart fundamental collegiate instruction in the principles of the use of English in public speaking in the fundamental viewpoints of economics—in addition to theoretical preparation in medical and nursing courses.

It is incumbent upon the school of nursing to develop to instill into its students and to foster in them the ideals of the nursing profession. From her studies there should develop in the mind of the thoughtful student at least the beginnings of a formulation of the nurse's place in the nation's life. And from that understanding there will be derived a broader outlook on life, a deeper insight into the problems of mankind, a firmer grasp upon the fundamentals of living which enable the individual nurse to rise above those smaller annoyances concerning her employment, her hours of work and the nature of her work, which have in the past stood in the way of success of many creative endeavors in the field of nursing education.

Discussion

J. DEWEY LUTES, Chicago. One requirement for entrance into a school of nursing that seems to be generally accepted is that of a high school diploma—and rightly so. However, this must not be considered proof of a girl's ability to become a nurse. It is merely proof of her intellectual capacity to reach a certain level by way of a prescribed route.

We must make provision in our schools of nursing against the graduating of those who fail to acquire the proper attitude of mind. It is not enough to pour out instruction of which a sufficient amount can be retained in the memory to pass a written examination. We who administer in the schools of nursing must analyze students in such a manner that the failures are eliminated.

We must not permit education to stop at the end of the school career. We must encourage and put into operation some plan whereby the individual will continue to learn and improve herself and her profession as the years pass.

The members of the faculty must be selected on the basis of their ability and fitness in this special field. And graduate nurses must be selected for departmental positions in the same careful manner in which a student is admitted to the school.

DEPRESSION DEVELOPMENTS IN RELATION TO HOSPITAL ECONOMICS

B C MacLEAN M.D. New Orleans. More attention has had to be given during the depression period to the economies of hospital operation as a result, many new experiments have been tried. It was inevitable that some startling schemes would be advanced in a frantic attempt to bolster revenue. Hospitals have been advised to open beauty parlors, barber shops and soda fountains. It is wise to remember that a hospital should not stray too far from its functional field even in times of depression. On the other hand, there are some profitable activities such as the operation of a doctors exchange or a nurses registry and the provision of office space for doctors which can reasonably be considered within the province of a hospital and which can be successfully instituted if local conditions permit.

Interesting to all hospitals is the success which has attended the inauguration of cafeteria systems for the feeding of employees, nurses, and internes. Another development has been the establishing of central supply rooms for surgical supplies and also central nourishment kitchens for the preparation and dispensing of the between meal extras.

Nursing education is more theoretical today than it was in the past. But the main purpose in any system of nursing education is always the same and cannot be too greatly emphasized—the *comfort and care of the patient*. It might help if our nursing faculties contained more bedside preceptors and less classroom Ph.D.s.

Hospital insurance although not a panacea for all our ills, seems to offer at this time the greatest promise of deliverance from economic pain. The medical profession should realize that hospital insurance plans, as at present conceived, offer a bulwark of defense against other radical trends which might revolutionize the practice of medicine.

The Federal Government itself has entered into direct competition with private hospitals in the care of veterans whose disabilities have been incurred outside any line of public duty either civil or military. It is to be hoped that the splendid efforts of the medical and hospital associations to stem this tide may be successful.

EFFICIENCY AND ECONOMICS AS APPLIED TO THE X RAY DEPARTMENT

EDWARD H. SKINNER M.D. Kansas City. In many localities there are several hospitals, none of which offers sufficient within its own walls to attract or pay for the full-time consultative service of a radiologist. With technical demands satisfied by a full time technician, one radiologist can easily serve at least four hospitals each day. Modern roads and rapid transportation make 50 mile trips as easy as any twenty five blocks in street car days.

There is no reason why the technicians in small hospitals should not serve both the radiological and pathological laboratories. Bookkeepers, record

clerks and operating room nurses may easily become radiological technicians without sacrifice to either service.

The compact arrangement of all laboratories and operating rooms would aid in the co-operation of technical assistants avoid many steps by many people concentrate and increase the demands for laboratory examinations promote more consultations between attending physicians and laboratory consultants eliminate the gossip infested doctors lounge rooms.

The sterile cystoscopic room can be adjacent to the X ray department and be served by the single X ray transformer for pyelograms. The plaster room can be next door and be served with fluoroscopic fracture service. The combined plate viewing and radiologist's office should contact the pathologist's sanctum to afford that co-operative consultative service so beneficial to attending surgeon, physician, and patient.

Economies in radiological fees can be effected by securing the co-operation of the staff in asking for radiological consultation for the particular diagnostic problem rather than making a blanket demand for extensive and costly technical procedures.

The co-operative fluoroscopic consultation of clinician and radiologist can be a great saving and afford increased values to the patient and greater glory to the hospital's reputation. Stereoscopy is beautiful but rarely necessary.

EFFICIENCY AND ECONOMICS AS APPLIED TO THE PHYSICAL THERAPY DEPARTMENT

JOHN S. COULTER, M.D. Chicago. It is possible for every hospital whether large or small to have a physical therapy department without the expenditure of a great sum of money if certain principles are observed. First of all, to be efficient a hospital physical therapy department must be under the control of a physician. In a large city this can be accomplished without any difficulty. In the smaller town where there is no physician devoting his time to physical therapy this department should be under the direction of the X-ray department.

The second requirement is well trained personnel. At the present time there is no course which definitely provides X ray technicians practical training in physical therapy. It is hoped that the societies of X ray technicians and physical therapy technicians can work out a satisfactory course of not more than 12 months to fulfill this need, inasmuch as many calls for technicians request an individual capable of taking charge of the technical work in both the X ray and physical therapy departments.

A hospital physical therapy department can be started without any apparatus except that made by the hospital carpenter, mechanic, and electrician. Proper equipment is essential for much of the needed treatment but no hospital should hesitate to start a department without equipment so long as available space is provided, and a physician is placed in charge assisted by well trained personnel.

In order to put before the hospital staff information relative to physical therapy one staff meeting a year should be devoted to the demonstration of the work of this department. Demonstrations should be scheduled for clinics lectures given to internes and nurses.

Records are the most important aids in the scientific success of a hospital physical therapy department. To be of value they must conform to the general record system of the hospital and form part of it.

EFFICIENCY AND ECONOMICS AS APPLIED TO THE ADMINISTRATION OF ANESTHESIA

JOSEPH MCNEARNEY M.D. St. Louis. In the present day the anesthetic department of a hospital should be staffed by physician anesthetists who have had special training in the field of anesthesia. There is a greater field for medical anesthetists now than ever before. The young medical graduate who will take special training in this field will be the anesthetist of the future. Medical schools are beginning to realize that a good knowledge of anesthesia is essential.

The nurse anesthetist is an economy to the hospital but not to the patient. The patient pays the same fee to the hospital for the anesthetic given by the nurse anesthetist as he would pay a physician anesthetist. In my opinion anesthetics should be on a flat rate fee basis, in keeping with the economic condition of the clientele of the hospital. The surgeon is then in a position to inform the patient what he will be charged for the anesthetic in estimating his probable hospital cost.

The hospital feels that it furnishes the equipment and materials and should be compensated for their use—which it should. Nevertheless the anesthetist is entitled to remuneration *in proportion to the amount of work done* whether he is working for the hospital on a salary or on a percentage basis.

A rather large savings can be made in the anesthetic department in the use of gases for anesthesia by having the proper preliminary medication and using soda lime filters.

EFFICIENCY AND ECONOMICS AS APPLIED TO THE ADMINISTRATION OF FOOD SERVICE

EUGENIA SHRADER St. Louis. With the present low price level of food commodities it is possible for certain savings to be made in the dietary departments of hospitals. The problem of the dietitian is how great a saving can she bring about without relinquishing her present standard of efficiency.

First of all, it is paramount that there be a well trained dietary staff to direct and help carry on the work of the department. With such a staff we know that only adequate diets would be considered in planning economical menus.

Since a centralized purchasing department is the general rule in most institutions it behooves the dietitian to be in close contact with this department.

To effect savings and add variety to her menu the dietitian must be responsive to any quick buys which the purchasing department feels advisable. On the other hand the purchasing department must be just as flexible and responsive to the needs of the dietary department.

The preparation and service of foods are exceedingly important. The dietary staff should ever be on the alert for variety in the preparation of food stuffs. Therefore, the kitchen should also be an experimental station where new recipes are tested on a small scale before being incorporated in the menu. This can be made a valuable part of the practical training of student dietitians.

The insulated cart seems to be the most efficient and economical means of serving food to the ward and also to the private patient. Astonishing savings can be effected by installing cafeteria service for hospital personnel.

The student nurse plays an important rôle in this economic readjustment. In the dietetic laboratory she should be taught the importance of a well balanced diet, how this diet may be adjusted to meet the demands of certain diseases. She should also be taught the value of food and food service from an economic as well as a therapeutic standpoint. The attitude toward food that the student nurse gains through her laboratory training and experience will be one of the deciding factors as to her degree of usefulness in the ward food service.

EFFICIENCY AND ECONOMICS IN HANDLING SURGICAL DRESSINGS AND SUPPLIES

SISTER PHILOMENA R.N. St. Louis. The hospital executive faces the problem of giving prompt efficient, adequate hospitalization to the sick of the community with less money than has ever before been at his or her disposal. Economy in the handling of surgical dressings and supplies can be made a great aid toward this end.

Adequate supervision of the preparation of supplies, their distribution and the procedures necessary for their repeated use and maintenance can be made to yield large economies.

Central distribution stations seem particularly economical. Such details as the size of the gauze packs, the carefully studied distribution of the packs to the various surgical units and attention to the special desires of the attending surgeons yield valuable results. If different grades of gauze are purchased for different purposes, economies are also bound to result. The preparation of Iodoform gauze drains cut into proper lengths minimizes waste, and through a practical method hospitals can easily effect the proper sterilization of such drains.

Savings can be effected in the preparation of physiological saline solutions if the needs of the various departments of the hospital are kept in mind in planning strength and size of containers. The proper handling of surgical needles and sutures reduces costs to rather an appreciable degree.

The use of packs, for example, for laparotomy operations, blood transfusions, etc. containing all the equipment usually found to be necessary for each particular operation, has also been found to result in diminution in costs.

Economical administration promotes co-operation within a department and thereby insures in increased efficiency.

GREETINGS FROM TRUSTEES OF THE HOSPITAL OF ST. LOUIS

SIDNEY ROTHCCHILD, St. Louis. Overexpansion and a disregard for the law of supply and demand prevalent in every phase of our national life affect hospitals in the same way as they do any other business organization or industrial concern. Market fluctuations that have affected business investments and wiped out fortunes have also resulted in a depreciation of hospital investments and greatly reduced the income from hospital endowment funds. Hospital trustees are keenly aware of the financial stress and of community needs at this time. Hospital administrators are business men and women. If they did not possess more than an average amount of business ability they would not be selected for their positions.

Trustees have a right to expect the most loyal co-operation from superintendents in their efforts to interpret community needs and safeguard community funds. They in turn, are under just as strong an obligation to be loyal and staunch supporters of the superintendents. We must realize that hospital superintendents have been working under a great handicap to maintain the same standards and service with a greatly depleted income.

Trustees, to whom the administrator is responsible for the execution of hospital policies, are likewise responsible to the community for the judicious expenditure of funds entrusted to their care. It is no small responsibility for regardless of whether the institution is tax-supported or non-tax-supported, the money comes from the community.

Lowered bed occupancy, hospital deficits, and other problems have created many perplexing situations and anxious moments for hospital trustees and administrators. The hospital as an educational health center is rendering a service that cannot be duplicated by any other institution. But is there any other institution that would be expected to serve the community month after month, year after year at a financial loss?

The hospital should not be less humanitarian in dealing with the public but more businesslike. We need more definite business policies in hospital management. There should be legislation, moreover to protect the hospital from exploitation.

CRITERIA TO BE OBSERVED IN SELECTING THE GOVERNING BODY OF A HOSPITAL

C. W. MUMFORD, M.D., Valhalla, New York: A governing body of a hospital to be promulgating must include variety in its membership as to age, sex,

wealth, social position, and business experience. We need straight thinkers on our boards, trustees who will consider matters not only in the light of business, but in terms of human values.

It is perhaps best not to include a physician on the board. Even though he may be entirely unbiased in his medical affiliations, the remainder of the medical staff usually resents his membership and loses sympathy with the purpose of the board. Wealthy men make valuable members if they are active. The ideal situation is to find a wealthy man who is definitely interested and willing to do his share of work.

Women should be represented on the board. It is well worth while, also, to have a representative of each class in community life. Therefore, a man who knows the needs of the working man and has his confidence should be made a trustee.

It is wise to give honorary membership to the principal officers of two or three prominent religious sects of the community. The hospital which can gain the endorsement of clergymen of all faiths will be more consistently supported by the public.

An ideal board of trustees would include an architect, a banker, a lawyer and a merchant. Care must always be taken, however, to make these trustees from the various walks of life understand that their firms are not to be preferred with the hospital's orders.

The greater his experience in large affairs and management of people, the more readily can the board member be trusted to act wisely in the performance of his duties. Persons of large affairs who have been accustomed to supervise or who have been a part in a working organization are to be desired. The surest way of gaining the interest of the trustee is to give him something definite to do and to keep him supplied with tasks to the extent of his willingness to work.

Care should be exercised so as not to select several persons who are closely related else the public will feel that one family is in control of the hospital. New members need to be educated in the history, the ideals, the traditions, and aims of the organization. We need more young, mentally alive citizens on our boards but they must not be the "go-getter" salesman and promoter type who refuses to act wisely and with reasonable deliberation.

If our board is carefully selected at first, if we maintain its balance as we make new appointments, it can, with the rarest exceptions, be depended upon to function for the good of the hospital and the community.

Discussion

FRANK C. RAND, St. Louis. Trustees should so guide the hospital that it will help the patient first. It is difficult but necessary that all of us should realize that each hospital patient is an entity within himself—separate and distinct from every other human being—and, so far as it is practicable and possible, should receive sympathetic individual attention and treatment.

A trustee must serve without salary must be a man of strong constitution of a low nervous organism, one who is not sensitive to sudden shocks and of fine recuperative powers.

It is short sighted to delegate to committees of the board—or for that matter committees of the staff—functions properly belonging to the administrative officer. Concentration of responsibility facilitates action for which credit or blame can be definitely fixed.

Various types of human activity differ mostly in form while in substance there is an underlying analogy that makes them closely akin. To the most casual observer there may be little resemblance between hospital trusteeship and the square circle but 18 years of experience has developed an empirical knowledge that forces on me the inevitable conclusion that they are of the same family.

RESPONSIBILITY OF THE GOVERNING BODY IN SELECTING THE SUPERINTENDENT

CHRISTOPHER G. PARWELL, M.D., Rochester, New York. It is important that members of hospital boards give careful attention to selection of their own membership. Hospitals both public and private are often greatly handicapped by the astonishing ignorance of members of their boards.

Attempts by boards to administer by committee or individual members the affairs of the hospital have proved inefficient and often disastrous. There should be no division of authority; administrative responsibility should center in a single individual who is employed for the purpose. Except for the executive committee, all committees should be advisory.

The superintendent should be regarded always as the agent of the board. He should be responsible for the employment of all department heads and should be consulted regarding appointments to the medical staff. He must be a leader and should be left free to make decisions for which he is always held responsible. A medical training is a distinct advantage. If a layman he should have access to medical advice, and ability to judge of its soundness. He must be alive to the problems of the medical profession and sympathetic with medical progress.

Until hospital boards generally appreciate the necessity for executives of real caliber and offer inducement in opportunities and compensation which will make hospital administration an attractive career the individual board will face its major problem when it becomes necessary for it to obtain the services of an executive who can be relied upon to direct the destinies of a modern hospital satisfactorily to its board, its medical staff and its community.

HOW HOSPITAL TRUSTEES CAN KEEP ABREAST WITH THE ADVANCES IN HOSPITAL ADMINISTRATION

MATTHEW O. FOLEY, Chicago. The best, most practical, and most satisfactory way for a trustee to keep abreast of the times in hospital administration

is for that trustee to attend board meetings regularly and listen to what the superintendent has to report. Besides giving an account of the current operation of the hospital, the progressive superintendent will try to help board members get an idea of trends and developments in the field and so attendance at a properly organized and well conducted board meeting is a practical education for a trustee.

Reading journals attending conventions and conferences, actively working on committees are most helpful in keeping the trustee abreast with the advances in hospital administration. But if the trustee will attend board meetings he will learn much about progress in the field of hospital administration which will make more valuable his service on the board.

There are far too many hospital boards which utterly fail to appreciate the responsibilities of their superintendents and the relation of the superintendent to the board. There are many hospital board meetings at which the superintendent is not permitted to be present, and there are too many hospitals in which the executive agent of the board is overwhelmed with detailed tasks ranging from fixing a broken down piece of equipment to collecting overdue accounts.

Too many hospital boards employ a superintendent presumably because they believe that this person knows more about hospital administration than any of their number and then they proceed to compel this superintendent to operate the hospital the way they want it operated.

If the superintendent is given a voice at board meetings that is heard with due attention, if he is not hampered with trivial details if he is accorded the co-operation and wholehearted support of the board he will be able to render better service to all concerned and so will improve the administration of the hospital.

REMOVING HOSPITALS FROM THE INFLUENCE OF POLITICS

JOHN A. McNAMARA, Chicago. Municipal county or tax-supported hospitals should be as much above suspicion as are our public schools and their administration should be on as high a level if possible on a higher level, because to hospitals is entrusted the task of returning to society the ill and the injured.

When mismanaged institutions in which graft is rampant in which death rates are high, and in which all ethics and standards of the medical profession are openly disregarded, are removed from the list of hospitals approved by the American College of Surgeons, from the list of hospitals approved by the American Medical Association for intern training, and from all other lists, then and not until then will the municipalities clean house and give to the taxpayers institutions wherein the indigent sick and injured may be cared for in an adequate manner.

It is an imposition on our young doctors and in terms to subject them to the influence of poorly equipped, managed, and staffed institutions. They can only learn vicious tricks and take away with them into practice a large number of false ideas and no ideals at all.

We must not neglect the health of the whole community we must not allow members of society to die because of improper treatment while we sit idly by and politicians fatten on the misfortunes of citizens. It is time that all good hospitals band together and protest that politically dirty and corrupt institutions are removed from the lists of accrediting organizations they must ask that a full survey be made of these institutions and that they be taken from the lists unless politics are completely divorced from all healing institutions.

DISCUSSION

EDGAR P. HOGAN, M.D., Birmingham, Alabama: It must be recognized that to remove hospitals from the influence of politics is a difficult problem. So many tax-supported institutions are still under political control because those who are responsible for the management of hospitals have not informed the people who are omnipotent in making laws, as to what form of government and administration is best for the hospitals.

It is by legislative enactment that laws must be secured which will stabilize hospitals in government and remove them from the destructive influence of politics. In many states, counties, and cities this has been done. Alabama many years ago by legislative enactment created a non-political board for the control of Bryce Hospital for the insane. The State Board of Health of Alabama and the boards in each county are elected by the state medical society and county medical societies, respectively. They have entire authority and responsibility for the public health work of the state and the expenditure of the public health appropriations.

For county and city hospitals a state law creating hospital boards consisting of five members, one of whom would be elected every 2 years for a period of 10 years, would be a most excellent one. Such a board would remove tax supported hospitals from the influence of politics.

Non-political boards of tax supported hospitals, clinics, and dispensaries can limit the work to charity cases only. Political boards cannot. It is in the interest of the tax supported hospitals, the taxpayers, politicians, private hospitals, the medical and nursing professions, and the general good that politics be eliminated absolutely from the control of hospitals.

HANDLING OF COMMUNICABLE DISEASES IN CONNECTION WITH A GENERAL HOSPITAL

T. R. PONTON, M.D., Augusta, Georgia: To accept and treat in a general hospital patients suffering from communicable diseases is a perfectly safe procedure, and in the smaller city where the num-

ber of such patients is not sufficiently great to warrant the construction and maintenance of a special hospital for communicable diseases, it is the logical method of protecting other members of the community while giving the patients proper care.

Correct diagnosis is the first great essential. It is the unrecognized case that infects others and may even cause an epidemic.

Proper prophylactic measures should be used. Hospital attendants whether they are to attend communicable diseases or not should have all the recognized forms of immunization unless they are known to be immune.

For the care of patients suffering from communicable diseases proper facilities must be afforded. Whenever possible each patient should be placed in a room by himself. Failing the individual room, the next best facility is the cubicle in which a definite space is allocated to each bed and a partial partition placed at each side of this space. When the cubicle cannot be provided patients can be accommodated with safety in the general ward so long as they are grouped properly and the beds spaced sufficiently apart.

Antiseptics should have little place in the management of communicable diseases. For sterilization of some articles used around the patient they are necessary but the basin of bichloride so frequently seen at the bedside is a menace which should be avoided. It gives a sense of security which is absolutely false.

Soap and water are the key to proper technique. For 15 years I have used soap and water with cross-infection so rare as to be negligible. If one factor could be selected as the most important it would be running water. If you use plenty of soap and water and follow the dictates of medical science in measures of prophylaxis, you may be assured that in the general hospital patients known to be suffering from communicable diseases may be cared for with perfect safety to other patients and to attendants.

DISCUSSION

WALTER C. D. KIRKNER, M.D., St. Louis: While it may be true that communicable diseases may be treated in general wards of hospitals in smaller communities, I believe that in the larger cities it is distinctly desirable to establish and maintain separate isolation wards.

A careful diagnosis relative to infectious diseases is most important. No patient should be admitted to the general wards or open services where there is a suspicion of communicable disease. Cases that are suspicious, such as typhoid, measles, diphtheria, etc., should be very carefully examined so that proper assignment to the ward or division may be made.

In the City Hospital, for instance and especially in the children's ward, all children are isolated in rooms for a certain period until it is ascertained that infectious diseases may be ruled out. It is important that preliminary examinations such as throat cul-

tures blood cultures etc. be made at the earliest possible moment so that the possibility of infection may be determined.

Unless the hospital is provided with proper facilities for handling communicable diseases it is difficult to prevent the spreading of contagion. Chlorinated lime is an important preparation in handling infectious diseases because it has a distinct antiseptic value and can be used readily and easily.

THE INDIVIDUAL DOCTOR'S RESPONSIBILITY FOR CLINICAL RECORDS

WALTER F. COLF, M.D. (Greensboro, North Carolina). We as physicians are responsible for clinical records. We are not only responsible, we are obligated first of all to our hospital organization. The standing of a hospital in a community affects the standing of its staff. Its organization depends upon the loyalty of its members.

We are obligated to our colleagues, especially to the future physicians now in the making. Careful directions and records of the blunders we have made will act as a beacon light to warn them of impending danger.

The records that we make are future protection to ourselves in legal matters. Again it gives us a better grasp, a broader viewpoint of our case which enables us to formulate a clearer and more concise idea of the pathology involved. When we make a record of a case we are writing the life history of our association with the medical profession.

Our obligation is greatest to our patients. Every patient is entitled to a careful and concise record of our findings so that in case of necessity it may be used to his advantage in the future. The record enables the physician to make a finer diagnosis of his case and thus to better fulfill his duties as consultant and surgeon.

Do you direct your staff to make these histories because they are required by the American College of Surgeons or do you insist upon them because of the value of the record? Has it ever occurred to you to meet with the staff of your hospital bringing with you the criticism of your records by the American College of Surgeons for discussion so that better co-operation may be enlisted? It should be remembered that one of the chief criteria upon which the American College of Surgeons classifies your hospital is based upon the completeness, clearness and accuracy with which you record the work accomplished by your staff.

Discussion

DEWELL GANN, JR., M.D. (Little Rock, Arkansas). There is no department in the hospital where the co-operation of the doctor is more essential than in the record room. Here the doctor and the record librarian need the help and co-operation of each other in order to secure records of efficient clinical value. The record librarian of today invites and appreciates constructive criticism of her department. She realizes that without such criticism

from the doctors who are in a position to recognize the scientific value of a record, her records will be valueless. No matter what amount of ability the record librarian possesses or how progressive she may be she cannot succeed in producing scientific case records without the intelligent and vigilant co-operation of every doctor.

Just as the officials of any commercial organization are entitled to know the reasons of the profit and loss in the business, so also the hospital management has a right to an accurate and honest report of the medical service rendered in its hospital. Medical science will be advanced by the accumulation of such data. Authoritative statistics of one hospital combined with those of other hospitals will furnish material for research. As practically all advancement in medical science has been achieved through research work, it is the duty of every doctor to contribute his knowledge to its promotion. Although hospital records have been greatly improved in recent years, they are still found to be inadequate as has been highly emphasized in the present research work on cancer. In order to overcome this disadvantage the American College of Surgeons has adopted special cancer sheets which are well worth consideration.

An office-hospital routine which I prepared and am still using at St. Vincent's Infirmary is outlined here in the hope that it may be helpful.

1. During the examination of a patient in the office I dictate in code to a nurse the working diagnosis and what I propose to do.

2. When the nurse takes the patient into an adjoining room so that his clothing may be adjusted, she prepares an admission slip in code which the patient takes to the hospital with instructions to hand it to the record clerk on arrival.

3. After the clerk at the hospital has assigned the patient to a room the slip is handed to a graduate nurse in charge of my patients at the hospital who transfers the working diagnosis on the slip to the progress record together with my recommendations for hospital procedure. I need not see the patient further that day unless I so desire, and the following morning the chart is brought to the operating room with the patient. It is only necessary for me to consult the progress record to know what I am to do for the patient and unless I have been notified of some oversight or irregularity I know the patient is ready for operation.

4. On completion of the operation I dictate to a dictaphone the postoperative diagnosis, findings and procedure.

5. After the morning work is completed, the hospital stenographer transcribes the dictation to the operative chart and this becomes a part of the record.

6. When the patient is discharged from the hospital my nurse prepares a card, similar to the usual summary card which is sent to my office for ready reference containing all necessary data for essential follow up, financial and otherwise.

This system takes care of all essential data except the history, physical examination, and laboratory work at the hospital.

THE VALUE AND SCOPE OF MEDICAL SOCIAL WORK IN THE HOSPITAL

GRACE BEALS FERGUSON St. Louis. It is true that medical social work has made its most significant contribution in the study and treatment of medical rather than surgical problems. The reason for this is perhaps obvious, in that medical problems are much more frequently complicated by personal and environmental situations than are those dealt with by the surgeon. The treatment of diabetes or tuberculosis, for example, depends upon the emotional acceptance of the regimen, the economic status, and the participation by the patient to a far greater degree than does the treatment of a fracture.

There are, however, two aspects of surgical treatment to which experience has shown that the social worker can make a valuable contribution: first in regard to follow-up and second, in regard to the adjustment of mental and emotional concomitants which we know today can seriously complicate the treatment of patients cared for by a surgeon.

Social studies have shown that efforts on the part of the social worker to secure the return of a patient for a follow-up examination after a period of time has elapsed are usually unsuccessful. On the other hand if the social worker interviews the patient when he is first being admitted to the clinic or hospital, lapses and failures to return decrease noticeably.

It is the social worker's responsibility to counteract any adverse objective factors in the patient's environment. She can be of untold assistance to the surgeon in helping the patient adopt a better mental attitude toward his condition, and encouraging him to co-operate with the doctor and the hospital so that his recovery from the operation may be effected in as brief a time as possible.

DISCUSSION

ROBERT E. NEFF Iowa City, Iowa. Time was when the hospital was merely a boarding house for the sick paying no more attention to its discharged patients than hotels today pay to their departing guests. The hospital should be vitally concerned in the discharged patient and assume responsibility to the extent that interest is maintained in the patient until he becomes restored to a normal social environment after leaving the hospital.

The follow-up work on discharged patients is the direct responsibility of the social service department and enable the hospital to round out the treatment of patients and restore them to normal environment in other words, finish the job. Without follow-up work on patients, the hospital has no assurance that the job has been completed and may expect to have back on its hands many patients whose hospital treatment has been for naught, chiefly for the reason that proper control during

convalescent care had not been exercised over the social factors necessary for a complete cure.

To handle this problem adequately for the hospital, there must be trained workers who possess specialized training in the basic principles of social work, together with knowledge bearing on etiology, methods of treatment, and prognosis in the various diseases. The proper handling of the patient from the standpoint of social needs must be based largely upon medical factors of which the social worker must have at least a general knowledge and which must be supplemented by the directions and findings of the physician.

Many hospitals have established social service departments on the justification of economic considerations. Financial investigation of prospective patients by social service has rendered very definite financial benefits to the hospital. Also, the matter of the rapid turnover of patients which represents an economic factor of no small importance, is greatly aided by social service.

If we are to treat the patient as well as the disease, we must treat him personally emotionally and socially—this may be accomplished through the means of well trained and experienced social workers.

HOW THE MEDICAL SOCIAL WORKER CAN ASSIST IN THE PRESENT ECONOMIC SITUATION

RUTH LEWIS St. Louis. The time at which the social worker touches most directly the economic affairs of the hospital is on the admission of patients. This is not a routine procedure, and because of its large social components may logically be performed by a social worker. She may determine the patient's eligibility for admission, set the rate he is to pay and as well influence the collection of the account.

At a time when free and part pay beds are at a premium the selective utilization of those available is a grave responsibility of the hospital even though the choice of who shall occupy a particular free bed may not swell the income of the hospital. The medical social worker either through her previous contacts with the patients in the clinic or her relations with other social agencies may be able to contribute information about the patient which will help to make a wise decision regarding his admission.

The pressure on the free and part pay beds may be partially relieved in many hospitals by the efforts of the social worker in reducing the length of stay of patients. In cases where a close working relationship exists between the physician and the social worker and a plan for the after-care of the patient has been made before the patient's admission or early thereafter the average length of stay has been markedly reduced.

When patients are refused admittance to the hospital and feel that they are being unreasonably treated because the hospital is not full and is partially supported by the community it is the social worker's problem to interpret the hospital's present situation and demonstrate convincingly the practical alternative of home care.

It is in service to patients that the social service department makes its greatest contribution to the hospital. In order to insure complete treatment to its patients the hospital must know the social situations complicating medical care. These the medical social worker supplies. She is also interpreting the hospital's financial limitations and needs. The family, the employer, the minister, the school teacher, the lodge brother, the judge, the family physician are all channels through which the social worker may pass on this information of the hospital's services and needs through her daily contacts on behalf of individual patients.

THE RÔLE OF THE SOCIAL WORKER IN THE DIAGNOSIS AND TREATMENT OF CANCER

ELEANOR COCKERILL, St. Louis Cancer a disease ranking second as a cause of death in the United States offers a real challenge to the social worker. As the medical profession seeks to perfect the diagnosis and treatment of this disease there is an increasing realization of the vital influence of the social factors which are involved.

The social worker's task is to understand as completely as possible the problem of each individual patient. She arrives at this understanding by acquainting herself with the details of his physical condition—the type and stage of the cancer, the therapy advised, and the possibility of arrest or cure—and by inquiring into his social situation which enables her to evaluate the possible effect of the disease and the obstacles to treatment and observation which may arise. With this information in her possession, she is equipped to bring to the aid of the surgeon any pertinent observations she has made which have a bearing upon his plan. She becomes adviser and interpreter to the patient and his family supplementing earlier explanations by the surgeon, anticipating and meeting difficulties in carrying out the plan of treatment and bringing into action any other social adjustment indicated. Community contacts are strengthened and new resources enlisted.

If the social worker is successful in her rôle, there will be no necessity for the follow-up of delinquent patients. The foundation she lays through interpretation and guidance is permanent and lasting. The surgeon will be able to complete his diagnostic study to carry out a plan of treatment and observe the results through the years which follow. As the social worker carries on her program with the patients assigned to her care, she becomes an effective channel through which information about cancer can be disseminated to the general public. She thus contributes to the diagnostic, treatment research, and educational phases of the cancer program through her rôle as interpreter to surgeon, patient, and community.

Discussion

FRANK L. RECTOR, M.D. Evanston, Illinois
Granted the co-operation of the attending phys-

ician which it is inconceivable not to have the problem of the social worker is to bring to the physician and the hospital regular reports of the health and welfare of the patient. No fixed rules can be laid down by which this may be done. It is largely dependent upon the common sense of the social worker and her ability to take advantage of all resources that will be of assistance in her work.

The social worker is aided greatly in her work if she is also a trained nurse. She can then evaluate the conditions with a professional eye as well as with her social training and can thereby render a twofold service that is of special value.

In almost every instance it is best to tell the patient that he has cancer. This is now done in some hospitals doing cancer work and results in the best co-operation between the staff and the patients.

Should convalescent cancer patients, especially hopeless cases, be cared for in the hospital or in their homes? One large cancer hospital, the Memorial Hospital in New York, has answered this question by getting such patients out of the hospital at the earliest possible moment and back at home among friends and relatives. Here they are cared for by home visitors, trained nurses with experience in social work. These visitors render a splendid service by their regular visits to these patients at times only for a friendly call and again as nurses to render such professional care as is indicated. The medical staff of this hospital has repeatedly stated in public that it would never recommend special cancer work in any hospital unless and until such a follow up is available in the homes of its patients.

A MODERN MEDICAL AND SURGICAL CHEST SERVICE AT BARNES HOSPITAL

JACOB J. SINGAR, M.D., St. Louis That the medical and surgical chest service at Barnes Hospital was begun in a space formerly used as a storage room for trunks is ample evidence to prove that good work can be done with limited facilities as long as the personnel is properly trained and equipped.

Particular emphasis has been placed upon the study of the lungs in this department but the scope of thoracic surgery is by no means confined to these organs. Because of the development of safe surgical methods of approach and attack, not only do the various parts of the lung respond to surgical measures, but even intrathoracic tumors can now be safely removed and even certain conditions of the heart can be attacked successfully.

At the present time we have a large X-ray room well ventilated, two operating rooms connected with the fluoroscopy room which are connected with the chest radiographic room. The rooms are wide enough so that a patient can be moved from the various rooms without having to be lifted and all necessary examinations and treatments made. A large right-angled corner, used as a passageway to and from the fluoroscopy room, has been

boxes and stereoscopic apparatus the walls have moldings so that exhibitions of unusual chest photographs can be displayed for meetings and conventions. Private offices for the medical staff and secretary and a large classroom and dressing rooms complete the physical equipment.

The second floor of the new Rand Johnson Memorial Building of Barnes Hospital was set aside for patients requiring treatment in the thoracic field. This floor is connected by halls with the diagnostic service. It is modeled after the best tuberculous sanatoria with porch facilities for all patients. A graduate nurse especially trained in thoracic diseases, spends her entire time in the chest service and a secretary looks after records, lantern slides, and teaching paraphernalia both add greatly to the usefulness of this division for purposes of training and instruction. A special library in this field is rapidly becoming accumulated.

The chest floor in the Rand Johnson Memorial Building furnishes the best possible conditions for the care and treatment of chest patients. The facilities for isolation is flexible so that the number of patients can readily and on short notice be increased or diminished. It is so arranged that patients desiring or needing accommodations varying from the free ward patient, ward pay patient, semi-private patient to the private patient can be received the time of the professional personnel including the visiting doctors, internes, nurses, dietitians, attendants, orderlies in fact all who come in contact with the patients, is conserved to the greatest possible extent.

D & S 10A

LOUIS H. BURLINGHAM, M.D., St. Louis: Shall patients with tuberculosis be admitted to general hospitals? Outstanding authorities on tuberculosis are agreed that tuberculous patients should be ad-

mitted to general hospitals where provisions can be made for their care.

Sanatoria are often too far removed from large medical centers. Moreover the close connection of the large community hospital with teaching facilities makes it possible for future medical men to have the benefit of learning how to diagnose and treat such cases under discussion.

It is necessary for the general hospital to meet the advances made in thoracic work and to adopt the proper facilities in line with changing conditions.

EDITORIAL NOTE—Two afternoons during the Hospital Conference were devoted to round table conferences dealing with administrative, professional, economic, and social problems affecting hospitals. The Tuesday session was conducted by R. C. BURKE, M.D., Madison, Wisconsin, superintendent, State of Wisconsin General Hospital; the Wednesday session by ROBERT JOLLY, Houston, Texas, superintendent, Memorial Hospital.

Thursday, October 20, the closing day of the Hospital Conference, was given over to departmental demonstrations in the Jewish and St. Mary's Hospitals, conducted by the superintendents with heads of departments, and included the following demonstrations and discussions: preparedness for emergencies in hospitals; operating room management and procedure in handling major operations; food service with various types of tray set-ups; general and special or therapeutic diets; handling supplies; staff education and nurses conferences; organization of the hospital with exhibition of organization charts; admission of patients with complete procedure; nursing administration and nursing service problems associated with clinical records and complete record system; organization and management of the pediatric division with demonstration of certain procedures.

PARTIAL PANCREATECTOMY IN CHRONIC SPONTANEOUS HYPOGLYCEMIA

WITH A REVIEW OF THE CASES OF HYPOGLYCEMIA SURGICALLY TREATED

EMILE HOLMAN M.D. F.A.C.S. AND O. C. RAILSBACK M.D. SAN FRANCISCO, CALIFORNIA

From the Departments of Surgery and Medicine, Stanford University Medical School, San Francisco, California

THE specific treatment of diabetes, or hypoinsulinism, with insulin has inevitably led to a knowledge of its counterpart hyperinsulinism. Indeed it is said that certain investigators long preceded Banting and Macleod in the discovery of a pancreatic substance so potent in its correction of diabetes that it had to be abandoned mainly because of the convulsive seizures that attended its administration.

Hyperinsulinism produces a train of symptoms, the severity of which is directly proportional to the insulin excess and the resulting hypoglycemia. Three surgical conditions have been recorded in the literature as being responsible for this insulin excess:

1. Metastasizing tumors or carcinomata of the islets of Langerhans which, contrary to the usual carcinoma of secreting glands, have retained their normal property of producing insulin.

2. A benign tumor or adenoma of the islets of Langerhans, comparable to an adenoma of the thyroid.

3. An overactivity of an otherwise normal appearing pancreas comparable, as pointed out by Wilder, to hyperthyroidism due to hyperplasia.

Within the last 8 years all three conditions have been subjected to surgical intervention

with amelioration and, in a few cases, complete cure of the disease. The following brief summaries of these recorded surgical cases illustrate the characteristic symptoms accompanying this rather recently recognized clinical entity.

CASE 1 (Mayo Clinic.) Carcinoma of the islands of the pancreas. Hyperinsulinism and hypoglycemia. Wilder, Allan, Power, and Robertson. *J. Am. M. Ass.* 1927 lxxxix, 348.

A physician, aged 40, 18 months before admission to the Mayo Clinic began having sudden attacks of faintness and weakness, with parasthetic numbness of the tongue and lips. As time passed these attacks occurred more frequently and were more severe, producing greater weakness, profuse perspiration, and trembling. They came when meals were delayed or if unusual exertion was undertaken and the patient himself discovered that he could prevent them by eating between meals and by taking sweet drinks. The first attack resulting in collapse came in November 1925. The patient had been operating later than usual and, being overtaken by weariness, was soon mentally confused and collapsed in a stupor. Attendants thought he had lost consciousness, but he was able to swallow an egg nog which an assistant gave him and in a few minutes had completely revived.

As time passed, the tendency to hypoglycemia increased so that the interval between the patient's taking food had to be decreased and it became necessary for his wife to watch when the patient slept and put candy into his mouth at the first sign of unusual behavior. For the purpose of studying the hypoglycemic reaction, after the mixed noon meal

of October 31 sugar was withheld. The patient remained in bed under constant observation. The systolic blood pressure was 110 and the diastolic 60. The first symptoms appeared 3 hours and 30 minutes after the meal, when the blood sugar had fallen to 0.055 grams per 100 cubic centimeters. There was a sense of apprehension and depression with vague paresthesia. Fifteen minutes later perspiration and tremor were noted. At 4 hours the blood sugar had fallen to 0.036 grams per 100 cubic centimeters, the face twitched, speech was incoherent, and the systolic blood pressure was elevated to 134 while the diastolic remained at 60. At 4 hours and 15 minutes the blood sugar reached 0.027 grams per 100 cubic centimeters, the patient was stuporous and no longer able to speak, tossing about with irregular, convulsive jerking that affected the entire body. Fifteen grams of dextrose were fed by mouth, and in 10 minutes rational conversation was resumed. The blood sugar was 0.063, the systolic blood pressure was 122 and the diastolic 48.

In this instance the administration of epinephrin had little effect as compared with experience in other cases. One milligram of epinephrin was administered at a time when the patient was beginning to manifest symptoms of hypoglycemia and when the blood sugar was 31 milligrams per 100 cubic centimeters. The symptoms were not affected and sugar had to be given 4 minutes later to prevent collapse. Pituitrin injected when the blood sugar was low caused symptoms to appear and 40 minutes later a second injection was made. Sugar was required within 5 minutes after the second injection.

At operation, December 4, 1926 a hard firm nodular pancreas was felt and several nodules in the liver. At his death a month later a carcinoma of the islands of Langerhans with metastases to the liver was found. The carcinomatous tissue from the liver yielded at least 40 units of insulin for each 100 grams. It is of interest that before operation the ingestion of 30 grams of dextrose an hour was necessary to avoid symptoms of hypoglycemia, whereas just before death 1000 grams of sugar were required daily.

CASE 2 (Union Memorial Hospital, Baltimore.) Resection of the pancreas (Finney and Flannery) Ann. Surg. 1928 lxxxviii, 584.

A woman aged 53 years, entered the hospital in December 1927 with the complaint of spells of confusion, with mental lapses and strange behavior. Her illness had begun 4 years previously coincident with her menopause. At first the attacks were slight and infrequent. It was noted that she would seem dazed, could not concentrate or think clearly and sometimes would see double. The attacks at that time would be of but a few minutes duration, with no after effects. After a year and a half, she became alarmed about her health, and went to Europe for a rest. During the year spent there, there were about six or eight attacks. They usually occurred before breakfast, but had not as yet come to be definitely associated with the taking of food. Any alarm or

trouble might precipitate an attack. Once or twice she fell while walking, but was conscious of no dizziness, and was able to arise immediately and continue. During the 18 months preceding admission the attacks had increased rapidly both in number and severity until they had become daily in occurrence, usually before breakfast.

A typical attack was described as follows: diplopia and great difficulty in properly focusing her eyes were often the initial symptoms. Then the head began to jerk unsteadily and roll from side to side. At the height of the attack, she screamed and threw herself violently about. There was at times some frothing at the mouth. There had never been any biting of the tongue, or other physical injury during an attack, nor any loss of sphincteric control. Everything that occurred during the attack was hardly remembered by the patient afterward. She felt exhausted, both mentally and physically. The attacks lasted from 15 minutes to several hours. Upon one occasion she said she was semi-conscious for a whole day. The most interesting feature about these attacks was that they were aborted in a few minutes if, at the first warning of their approach, the patient took a few mouthfuls of shredded wheat biscuits and cream. From September to December 1926, while under treatment at a sanatorium on forced feedings and brouides, she had no seizures at all.

A number of blood sugar estimations had been made during the period of her illness: September 1925 133 milligrams per 100 cubic centimeters; September 1926 41 milligrams per 100 cubic centimeters; October 1926, 79 milligrams per 100 cubic centimeters; May 1927, 30 milligrams per 100 cubic centimeters. The basal metabolic rate was -9 and -6 on two examinations. Other laboratory examinations were practically normal.

Ten units of insulin were given hypodermically with the immediate production of an attack. From this attack she recovered with equal rapidity following the intravenous injection of a glucose solution. On another occasion, 10 units of insulin were given intravenously together with 20 grams of glucose, without the production of an attack. At the time of these experiments, the blood sugar was at a normal level before the insulin was given. During the attack, it was very low from 20 to 30 milligrams per 100 cubic centimeters. Immediately after recovery following the injection of the glucose, it had again become normal. On the other hand, at another time while in the fasting state, with a very low blood sugar a hypodermic injection of 10 minims of adrenalin prevented the occurrence of an attack, and an hour later the blood sugar was found to be normal. The same result was obtained by the injection of pituitrin, hypodermically and, also though less promptly by the use of pituitrin intranasally. Epinephrin solution had no effect whatever in warding off an attack.

At operation, December 8, 1927 the pancreas and liver seemed normal in size, shape, and consistency.

Owing however, to the persistent unexplained hypoglycemia it was decided to resect a portion of the pancreas. Accordingly, beginning at the tail, the pancreas was mobilized and dissected out of its bed until approximately two thirds of it had been freed. When as much of the pancreas had been mobilized as it seemed wise to remove—approximately 22.5 grams—the body of the gland was divided by a V-shaped incision and the resulting flaps of pancreatic tissue were brought together and sutured with continuous plain catgut which effectually covered in all the raw surfaces and controlled the oozing therefrom. On microscopic section the removed tissue was apparently normal pancreas.

After operation the blood sugar varied from 45 to 70 milligrams per 100 cubic centimeters. From December 12 to December 20 the patient had light attacks almost daily usually the first thing in the morning occasionally at other times during the day. None of these attacks were severe nor did they progress beyond the point of uncomfortable sensations with a peculiar staring expression of the eyes, facial grimacing and general restlessness. At all times, the administration of a few drams of glucose immediately aborted an attack.

On the eighteenth day after operation there was a severe attack which subsided promptly on taking a few mouthfuls of shredded wheat sugar, and milk. It was followed by a crying spell, and the patient was very much depressed for the rest of the day. A venous puncture was done during the attack and the blood sugar was 30 milligrams. It would appear that not sufficient pancreas had been removed to control adequately the hyperinsulinism or a small adenoma had been overlooked.

CASE 3 (Stanford University Hospital.)

A man 31 years old entered the hospital on May 6, 1928 with the complaint of spells of unconsciousness. His past history was unimportant. His illness dated back one and a half years when on several occasions he was compelled to quit his work late in the morning because of pronounced weakness. He recalls one occasion when he became groggy but did not lose consciousness. About one year ago after a morning's work in the field and while returning to the house his legs became quite weak causing him to stagger. This was associated with mental confusion and disorientation followed by collapse and loss of consciousness. He was given a cup of hot chocolate following which he recovered immediately. Similar attacks occurred at infrequent intervals usually after several hours of hard work, and they were always relieved by taking food. On one occasion after attending a dance he failed to awaken in the morning and could be aroused only after food had been administered.

At the onset of the illness the attacks occurred at intervals of 1 to 2 months but after 4 months they occurred once in every 2 or 3 weeks. It was about this time that the patient associated the attacks with the need for food and thereafter he was able to abort or prevent them by eating. As time passed the at-

Fig. 1 The course of the blood sugar during a 20 hour fast. Supper was omitted the evening before with breakfast on the day of the fast. The vertical line represents the milligrams of sugar per 100 cubic centimeters of blood. Note that a blood sugar of 35 milligrams rose to 74 milligrams following the injection of 0.5 cubic centimeter of adrenalin.

tacks gradually became more severe and more frequent, and on one occasion while in Central America he was placed in a hospital under observation. Here he was told that he had convulsions accompanying the attacks. He returned to the United States and entered Lane Hospital for treatment.

The physical examination on admission revealed no abnormalities. The Wassermann reaction was negative. The gastric acidity as tested by the alcoholic meal was normal. The spinal fluid showed three cells, negative Nonne and Noguchi reactions, the colloidal gold curve was normal and the Wassermann positive in the first two dilutions. The basal metabolic rate was -20 per cent. In view of the patient's history it was decided to observe his reaction to starvation. He was deprived of his evening meal. The following morning at 8:30 he was quite pale sweating profusely, tossing about in bed, laughing giggling and talking incoherently. He refused to answer questions. The eyes were staring or tightly closed, the pupils were dilated the pulse was rapid but not alarmingly so. As he refused to eat an attempt was made to pass a stomach tube, against which he fought viciously. He was finally left to himself and about 3 hours later when his tray was brought he roused sufficiently to take nourishment and within 10 minutes he was again normal stating he remembered nothing of the morning's episode.

The blood sugar during the attack was found to be 38 milligrams per 100 cubic centimeters. The blood sugar was then determined at intervals of 4 hours over a period of 24 hours. The patient was deprived of supper the evening before and given only breakfast on the day of the test. The results are shown in Figure 1. On the morning of the test, after 20 hours of starvation the blood sugar was 36 milligrams per 100 cubic centimeters. At this time he was conscious but definitely confused mentally. Following breakfast he was perfectly normal and at

12 noon the blood sugar was 125 milligrams per 100 cubic centimeters. During the day the blood sugar gradually fell and at 4 a.m. he was unconscious, lying quietly in bed, sweating profusely pale, his eyes rolling aimlessly about. The blood sugar at this time was found to be 35 milligrams per 100 cubic centimeters. After 0.5 cubic centimeter of a 1:1000 dilution of adrenalin hydrochloride, he recovered almost immediately and a blood sugar taken at this time was found to be 71 milligrams per 100 cubic centimeters. Two days later a sugar tolerance test was made. The fasting blood sugar was 60 milligrams per 100 cubic centimeters. One hundred grams of glucose were given by mouth and at no time for the succeeding 3 hours did the blood sugar reach 100 milligrams per 100 cubic centimeters, remaining constantly at about 80 milligrams per 100 cubic centimeters.

The patient was placed on a quantitative diet with a glucose equivalent of 401 grams including intermediate nourishment at 10 a.m., 3 p.m. and 11 p.m. During the next 3 days he felt fine and had no attacks. While he was on this high carbohydrate diet blood sugar estimations were done over a period of 24 hours. In spite of the high caloric diet and the frequent feedings the blood sugar never reached 100 milligrams per 100 cubic centimeters and the morning blood sugar after 9 hours of fasting was only slightly above 50 milligrams per 100 cubic centimeters.

In view of the low basal metabolic rate the effect of thyroid extract was tried. He was given 5 grains of Armour's thyroid extract daily and at the end of 8 days the basal metabolic rate was -3 per cent. During this time he remained on the same quantitative diet equivalent to 401 grams of carbohydrate. A series of blood sugar estimations made at this time when compared with those prior to starting thyroid were slightly higher during the day but the net result during the early morning hours was practically the same. In view of the fact that there was no appreciable alteration in the blood sugar or general condition administration of thyroid was discontinued.

In view of the probability that this patient was suffering from hyperinsulinism due to a tumor of the islands of Langerhans (pancreas) he was advised to have an exploration of the abdomen, but this advice was refused and he was discharged from the hospital on May 28, 1928.

The patient remained at home for a month, and felt fine on a diet with a carbohydrate equivalent of 355 grams including nourishment upon retiring. At the end of this time he returned to work. On the morning of the third day he failed to awaken and was roused only after being given nourishment. From this time on he had frequent repeated attacks following the slightest physical exercise. After further consideration he finally consented to operation, and he again entered the hospital August 8, 1928.

A series of blood sugar determinations done after 3 days on the former diet with a carbohydrate equivalent of 401 grams were practically identical with those done on the previous entry. His hourly consumption of carbohydrate was determined before operation so that a postoperative hypoglycemia might be avoided. A duodenal tube was passed and at fluoroscopy 4 hours later the bucket was seen in the duodenum. He was given 25 grams of glucose per hour through the tube. A blood sugar determination at the end of 5 hours was 95 milligrams per 100 cubic centimeters, at the end of 9 hours it was 88 milligrams per 100 cubic centimeters. Apparently 25 grams per hour was just below his carbohydrate consumption.

A laparotomy performed by Holman on September 1, 1928, revealed a normal appearing stomach, liver and gall bladder. The pancreas was exposed by dividing the gastrocolic omentum. It appeared normal and, although quite firm, no masses or abnormal densities were encountered on palpation. It did not appear abnormally large. The inferior border of the tail and body were easily mobilized, but the splenic artery and vein along the upper border with their numerous tributaries entering the pancreas effectively prevented the freeing of the upper border. Accordingly the splenic vessels were deliberately included in mass ligatures placed through the pancreatic tissue about 8 centimeters apart, and the intervening pancreas was removed. If the opportunity to resect a pancreas again presents itself I should be tempted to mobilize the spleen and remove it together with the pancreas, thus permitting complete removal of the tail and as much of the body as was thought necessary without the necessity of saving the splenic artery and vein. The stumps of the pancreas were covered with adjacent peritoneal folds, the rent in the gastrocolic omentum sutured, and the abdomen closed in layers without drainage. During the operation 3,000 cubic centimeters of a 5 per cent glucose solution was administered subcutaneously and immediately after operation 300 cubic centimeters of a 5 per cent glucose solution was given intravenously.

Microscopic study of the pancreas revealed no obvious anatomical abnormalities.

The immediate postoperative course was uneventful. Immediately after operation the blood sugar measured 450 milligrams per 100 cubic centimeters with a rapid fall during the first few hours to 100 milligrams per 100 cubic centimeters. During the 4 days following operation it gradually fell to 80 milligrams per 100 cubic centimeters where it remained for about one week with another fall to 40 to 50 milligrams per 100 cubic centimeters. At this time he again began to have slight mental confusion. On the thirteenth day after operation he complained of a fullness in the abdomen, and 3 days later a mass appeared in the epigastrium which was thought to be a collection of pancreatic fluid. On September 22 the abdomen was reopened through the upper part of the previous operative wound and 1,500 cubic

The increasing literature on diabetes of the islands of Langerhans suggests that the proper name "pancreas" be used to designate the position of the pancreas.

centimeters of a thick grayish fluid removed containing numerous necrotic bits of tissue which microscopically proved to be pancreas. It was obvious that the pancreas included in the transfixion ligatures had been digested away thus increasing considerably the amount of pancreas removed. Five small cigarette drains were introduced into the cavity and the abdomen was closed. During the next few days there occurred a profuse drainage of thin fluid containing many bits of necrotic tissue. This drainage gradually lessened and he was discharged from the hospital on October 6.

Following the second operation the fasting blood sugar remained low and as he continued to be on the verge of a hypoglycemic reaction each morning it became necessary to give nourishment during the night. After his return home he continued to give evidence of a glyopenic state in spite of nourishment during the night. On October 20 1928 a sugar tolerance test was again done and on comparing it with that before operation it was found that the blood sugar reached a higher peak but that at the end of 3 hours it was again back to 50 milligrams per 100 cubic centimeters.

The effect of pituitrin upon the blood sugar was then studied. A sugar tolerance was done in the same manner as before except that pituitrin extract (B. W.) 0.5 cubic centimeter was given hypodermally 15 minutes after the 100 grams of glucose. In Figure 2 is plainly seen that the peak value is much higher but the fall more rapid so that at the end of 2 hours 45 minutes the values are practically the same. He was then placed on pituitary extract (B. W.) 0.3 cubic centimeter 15 minutes after breakfast and dinner but as no beneficial effect on the blood sugar values resulted the pituitrin was soon discontinued.

Although complete relief from previous symptoms was not obtained immediately it was soon apparent that definite improvement had been effected. In April, 1929 he reported his hypoglycemic symptoms had been helped considerably. He was able to go through the day's work without leaving it to eat. In June, 1930, a series of tests at the Virginia Blason Hospital in Seattle showed the blood sugar at a higher level, and he reported himself much improved.

It is apparent, however that in a future comparable situation the removal of more pancreas would be indicated. A normal spleen is easily removed and to avoid any difficulties of hemorrhage from the splenic artery and vein, it would appear desirable to mobilize the spleen and the tail of the pancreas well up to the body making an attempt to reduce the size of the pancreas by two-thirds or three-fourths. If the analogy between hyperthyroidism and hyperinsulinism is applicable as suggested by Wilder, certainly a major por-

Fig. 2. Comparison of blood sugar curves after 100 grams of glucose with and without pituitrin. Solid line represents the blood sugar without pituitrin, the dotted line with pituitrin. The vertical line represents the milligrams of sugar per 100 cubic centimeters of blood.

tion of the pancreas must be removed to correct the hyperinsulinism. Moreover it would appear advisable also to introduce temporary drains to the operative bed to afford a removal of pancreatic secretion from the transfixed stump of pancreas, thus avoiding the complication experienced in this instance.

CASE 4 (Mayo Clinic.) Hyperinsulinism by Allan Arch. Int. Med., 1929 xlv, 65.

A farmer, aged 52 years, came to the Mayo Clinic in August 1928 because of attacks of weakness and stupor which had occurred at intervals for more than 2 years. On many occasions he had lost consciousness and had had convulsions. He noted that the attacks were most likely to occur if he had gone without food for several hours or if he undertook any exertion. He found that eating would relieve or prevent the symptoms, so he formed the habit of taking food at frequent intervals. As time went on the patient had to take larger amounts of food at shorter intervals. For several months before admission he had been obliged to eat at bedtime and during the night. He was unable to work, slight exertion, such as mowing his lawn, often precipitated attacks. Even when resting failure to take sufficient food resulted in attacks several times a week.

Investigation showed that when food was withheld, there was a gradual fall in the level of the blood sugar. If it fell below 0.06 per cent, the usual symptoms of hypoglycemia appeared. The lowest amount of blood sugar observed was 0.01 per cent. To prevent hypoglycemia food with the equivalent of 500 grams of dextrose each day was required, lunches being given between meals and three times during the night. The injection of epinephrin hydro-

chloride caused a rise in blood sugar and temporary relief of symptoms. Solution of pituitary had a similar influence although it was less powerful.

At operation, September 12 1928 the pancreas and neighboring organs appeared normal. The tail of the pancreas and part of the body were resected. The portion removed weighed 14 grams. Microscopic examination did not show visible abnormality.

Following operation, slight improvement was noted for a time, but in November, 1929, the patient described his condition as being similar to that before operation. He was obliged to eat regularly between meals, and once during the night.

CASE 5 (Toronto General Hospital.) Dysinsulinism. Convulsions and coma due to islet cell tumor of the pancreas, with operation and cure. Howland, Campbell, Malby and Robinson J. Am. M. Ass. 1929 xcii 674.

The patient, aged 52 years, complained in September 1922 of extreme exhaustion and attacks which were described as of minor and major character. Extreme faintness usually preceded the attack in which the patient became dazed, looked fatigued, and was restless. These minor attacks occurred so often at the table that it was suggested that the smell of food was a stimulus to insulin release. In the major attack, which might be preceded by diplopia or by a feeling of numbness in the legs, the mental confusion was deeper, she had to be placed in bed, where the grimacing became very evident. One could not arouse her although the eyes might be open. Her appearance was in some degree similar to that of an intoxicated person. Then the convulsion would commence with violent kicking, and tossing about of the arms and body, there being excessive secretion of saliva and incontinence of urine and feces. No degree of stimulus appeared to rouse her until the onset of sweating and vomiting, and then, soaking wet with perspiration, the patient would return to consciousness. Occasionally the patient became drowsy and slipped quietly into a coma to wake up later without any realization of the lapse of time or of events taking place during the comatose period. Following two of the severe seizures, the left arm and leg became paretic and, while this lasted only a few hours in the first attack, in the later one it remained some days, associated with thick, slurring speech.

Complete neurological examination was always negative. The blood sugar during a typical attack ending in unconsciousness was 0.04 milligrams per 100 cubic centimeters, and prompt relief was obtained by the administration of dextrose intravenously. A high carbohydrate diet plus three fourths pound sugar daily was required to keep her in a normal state. Five cubic centimeters of epinephrin restored the blood sugar from 40 milligrams per 100 cubic centimeters of blood to 110 milligrams within 000 hour. Solution of pituitary administered at a time when the blood contained 195 milligrams of sugar per 100 cubic centimeters blood caused the sugar to drop to 145 milligrams per 100 cubic centimeters.

At operation in March, 1929, a small tumor 1.5 centimeters in diameter was removed from the mid-portion of the pancreas, which was without capsule, and composed of masses of epithelial cells of the islet of Langerhans type diagnosed as carcinoma. Insulin was recovered from this tissue. No attacks occurred subsequent to the operation and the patient was at least temporarily cured.

This case constitutes the first successful treatment of an adenocarcinoma of the islands of Langerhans recorded in the literature.

CASE 6. (Barnes Hospital, St. Louis.) Hyperinsulinism from B-cell adenoma of the pancreas. Carr, Parker, Grove, Fisher and Larimore. J. Am. M. Ass. 1931 xcvi, 1363.

A youth, aged 19 years, entered the hospital January 1930, because of convulsive seizures diagnosed as epilepsy. About 1 year previously he had his first attack of unconsciousness in which his behavior was abnormal, and of which he remembered nothing. Other attacks followed at increasingly shorter intervals and became more profound and prolonged, and at the time of admission they were occurring almost daily, usually in the late morning, and especially during times of stress from school duties.

The attacks varied in severity but were essentially the same in character. They began with a feeling of queensness inside, a sense of hunger and anxiety. He became confused but would continue awkwardly in whatever he was doing. On one occasion, he drove for 45 minutes over busy city streets and had no remembrance of doing so. From confusion the attacks progressed into a stupor with profuse perspiration, slight cyanosis and, at times, more or less muscular movement. Recovery would occur spontaneously after a few hours and he was then tired and ravenously hungry. Food would promptly relieve the residual drowsiness. He had observed that an attack could often be aborted by eating candy and his mother had discovered that, if she could get him to take a few sips of sweetened tea at the onset of an attack, he would sometimes arouse sufficiently to finish the cup and the attack would be much milder. The anamnesis did not reveal any disorder of bodily functions between the attacks or otherwise during them.

Physical examination revealed normal condition in all essential details. During an attack of unconsciousness in the hospital, the blood sugar determination showed 44 milligrams per 100 cubic centimeters. Five grams of dextrose introduced intravenously brought a prompt return of consciousness. For a time a diet rich in carbohydrates caused almost complete relief of symptoms but by October a definite increase in severity of symptoms prompted surgical intervention. At the operation on October 23 1930, the pancreas was exposed through the gastrotomic omentum and revealed in its midportion a firm bluish mass 2 centimeters in diameter which

was easily enucleated. No leakage of pancreatic secretion occurred. Following operation the blood sugar determinations ranged from 107 to 92 milligrams per 100 cubic centimeters and no further attacks occurred. The tumor was composed of B cells of the island of Langerhans type.

CASE 7 (Barnes Hospital St. Louis.) Adenoma of the islands of Langerhans with hypoglycemia. Womack, Guagi and Graham. J. Am. M. Ass. 1931 xlvii 831.

A farmer aged 44 years one morning while doing chores before breakfast noted a mental confusion comparable to intoxication which was completely relieved by eating breakfast. A second similar attack a week later was followed by increasingly severe seizures resulting finally in periods of unconsciousness controlled completely by giving food. Various examinations were made and a tentative diagnosis of brain tumor suggested. The attacks then appeared before rising in the morning characterized by mental confusion, talking at random and twitching movements especially about the face. Symptoms apparently referable to the gall bladder developed, for which the gall bladder and appendix were removed without relief. His wife then noted that repeated feedings during the night and the frequent ingestion of candy during the day prevented the attacks.

Physical examination was practically negative. The basal metabolic rate was +3 per cent. After 9 hours of fasting his blood sugar dropped to 50 milligrams per 100 cubic centimeters of blood. In this state his face was expressionless, pupils dilated, speech incoherent. One hundred and twenty grams of dextrose ingested by mouth restored him to a normal state. At the end of 7 hours he was again mentally confused. Epinephrin was administered and there was a temporary relief from the mental confusion with a definite rise in blood sugar. At operation February 4, 1931 a small tumor only 0.5 centimeter in diameter was excised from the pancreas and following the operation there were no further attacks. A 12 hour fast brought on no symptoms and his blood sugar did not fall below 90 milligrams per 100 cubic centimeters of blood. The tumor proved to be an adenoma of the islands of Langerhans.

CASE 8 (Mayo Clinic.) Hyperinsulinism. Report of two cases. Allan. Arch. Int. Med. 1929 xlv 65.

A man, aged 47 years was first seen in October 1928, 4 years after the onset of weakness and stupor which was followed by convulsive seizures, disturbances of sleep and somnambulism. He noticed that eating relieved the symptoms or checked the attacks so that he began to take food three times during the night as well as between meals. In spite of precautions attacks of weakness and stupor occurred with increasing frequency especially after exertion and he was obliged to give up his work. About 2 months before admission he was in a hospital where food was not given after 5:30 p.m. Attacks occurred

during the night in which he became irrational and maniacal so that he was confined in a straight jacket on several occasions. Recovery occurred spontaneously after several hours.

Examination of the blood showed that the sugar content fell when food was not taken sometimes reaching 0.04 per cent. Hypoglycemic symptoms usually appeared when the blood sugar fell below 0.05 per cent. The ingestion of food with the equivalent of from 400 to 450 grams of dextrose prevented hypoglycemic symptoms when given at suitable intervals. Epinephrin and solution of pituitary showed transitory effects in checking hypoglycemia. Ephedrin also appeared to have some influence. At the operation sometime after his first admission the pancreas appeared to be normal. A portion weighing 8 grams was excised. Microscopical examination did not disclose distinct changes in the islands. The level of blood sugar fluctuated and was not below normal until the fifth day when the administration of dextrose was delayed until 11:30 a.m. The blood sugar fell to 0.066. From this time on food was given three times during the day and three times during the night. It was apparent that the tendency to hypoglycemia had returned. Convalescence was satisfactory but it was necessary to continue the regular administration of food. The condition since has been about the same as it was before the operation.

CASE 9 (Pennsylvania Hospital, Philadelphia.) Adenoma of the islands of Langerhans with associated hypoglycemia. McClenshan and Norris. Am. J. M. Sc. 1929 cxlvii 93.

A colored male of 41 was admitted to the hospital on December 15, 1927 with the complaint of attacks of loss of memory preceded for several months by a very queer feeling not accurately localized but apparently relieved by the ingestion of food. He was admitted in coma but within 1½ hours he had regained consciousness and was anxious to go home. A provisional diagnosis of epidemic encephalitis was made. Eleven hours after the usual hospital supper he was again in coma which continued until his death 70 hours after admission.

Three successive blood sugar estimations at 24 hour intervals were 30 milligrams per 100 cubic centimeters, 42 milligrams, and 38 milligrams in spite of the administration of glucose intravenously by gavage, and by rectum. The autopsy revealed a tumor of the midportion of the pancreas 15 by 7 by 16 millimeters in size, which had a delicate fibrous capsule, and the cells of which showed an alveolar arrangement, suggesting the adenomatous character of the lesion.

CASE 10 (Milwaukee County Hospital.) Carcinoma of the islands of the pancreas. Thalheimer and Murphy. J. Am. M. Ass. 1928 xci, 89.

A woman, aged 57 years, was admitted to the hospital in July 1927, in a stuporous state unable to answer questions but not unconscious. About 2½ years before admission she began to have attacks characterized by somnolence, followed by great

restlessness and irritability. The attack would last about one day, and on the following day she usually slept most of the time. In the beginning the attacks came at regular intervals, varying from 2 weeks to 3 months. During the last year they came more frequently and averaged about three a week until 2 month prior to entering the hospital, when she began to have them every day. For the past year epileptiform convulsions accompanied these attacks, but she did not form at the mouth or completely lose consciousness during the attack.

After entrance to the hospital the patient remained in a semiconscious state most of the time. The seizures came regularly every forenoon about 9 o'clock. They were not severe and were not accompanied by stertorous breathing, unconsciousness, cyanosis, or foaming at the mouth. Usually the attack lasted from 30 minutes to 1 hour. Following this she slept for a few hours but could be aroused. Although she perspired mildly after the convulsions, it cannot be said that this was more than a minor symptom of the disease.

Blood sugar determinations on July 12 were 60.6 milligrams and on August 13, 33.5 milligrams per 100 cubic centimeters of blood. During the second week of August the convulsions came on about three times a day; following each attack the patient sank into a state of coma and slept several hours. She died on August 18 after a prolonged state of coma.

At necropsy the pancreas showed a small tumor 1.5 by 1 centimeter, located about 4 centimeters from the tail end, incompletely encapsulated and invading the surrounding pancreatic tissue. A diagnosis of adenoma of the islands of Langerhans was made on the microscopic appearance.

It is apparent from the descriptions of the recorded cases that hyperinsulinism with its concomitant hypoglycemia is a recognizable clinical syndrome insidiously progressive in its course characterized by symptoms of weakness verging on exhaustion, nervous irritability and anxiety, easy fatigability, extreme hunger, muscular twitchings and tremors, imperfect and hazy vision, diplopia, unsteadiness of gait, excessive perspiration, loss of emotional control proceeding in the more serious cases to mental confusion, disorientation, epileptiform attacks, convulsive seizures, syncope, semistuporous states, coma and finally death. These are the exact symptoms noted clinically due to an overdose of insulin and are directly commensurate with the resulting hypoglycemia. Patients themselves frequently discover the beneficent effects of food in averting attacks.

Hypoglycemia has been described in other conditions as well. Josephs and later Griffith

described a series of cases of convulsions in infancy and childhood which they attributed to hypoglycemia, the etiology of which they did not understand. In a case described by Griffith a boy of 4 months suffered repeated convulsions which recurred at irregular intervals until at the age of 2 years and 4 months, it was suggested that they resembled those found in hypoglycemia. At this time during an attack in which he became unconscious, febrile, spastic, and vomited, an examination of the blood sugar showed only 20 milligrams per 100 cubic centimeters of blood. An intravenous injection of 100 cubic centimeters of a 10 per cent solution of dextrose resulted in prompt and complete recovery from this attack as also in four other similar seizures.

Cambridge and Wagner and Parnas have described cases of spontaneous hypoglycemia which they thought were hepatic in origin and Harris and later Jonas called attention to a remarkably lowered blood sugar in certain patients complaining of gastro-intestinal symptoms, weakness, and extreme fatigue. Subsequently Gougerot and Peyre and Sen draf and Planques made similar reports. Hyperinsulinism or dysinsulinism was advanced as the cause of these symptoms, but it remained for Wilder and his associates (Case 1) to present pathological proof of the association between spontaneous hypoglycemia and hyperinsulinism.

It is possible that another explanation for hypoglycemia lies in the experience recorded by Wadd in which a typical case of Addison's disease with destruction of the entire suprarenal system was characterized by severe comatose attacks accompanied by a pronounced hypoglycemia. These attacks were for a time aborted by administration of glucose.

Nielsen and Eggleston recently described 3 cases of epileptiform seizures accompanied by a lowered blood sugar and an altered blood pressure in which great improvement was obtained by frequent feedings and the administration of desiccated whole suprarenal gland by mouth. Frequent feedings alone did not work as well as when combined with the suprarenal gland. They postulated a dysinsulinism or hyposuprarenalism as the probable causative factors.

Several years ago a condition of hypoglycemia was demonstrated 18 hours following subtotal thyroidectomy for Graves' disease (5, 8). An antagonism between thyroxin and insulin has been hinted at by various writers, and it is suggested that the removal of a hyperactive thyroid gland results in a temporary overaction of its antagonist the pancreas. However, the interrelationship of the thyroid, adrenal, pituitary, and pancreatic glands is so intimate and the mechanism of their interactions with reference to sugar metabolism so obscure, that one can do little but theorize, and that not very intelligently. For the moment one can simply present the facts in the hope that they can be pieced together subsequently.

In the three instances in which small adenomata were removed at operation with complete recovery, one is surprised to find how small these tumors actually were. In the two cases from the Barnes Hospital Cases 6 and 7 the first tumor measured 2 centimeters in diameter, and the second only 0.5 centimeter in diameter. The case from the Toronto General Hospital yielded a carcinomatous tumor only 1.5 centimeters in diameter. Two other instances in which proved hypoglycemia existed before death Cases 9 and 10 yielded tumors only 1.5 centimeters in diameter. Shields Warren records 4 instances of so called adenomata of the islands of Langerhans found incidentally at necropsy measuring 1.7 millimeters, 1.3 millimeters, 1.2 millimeters, and 9 millimeters in diameter, respectively. These patients all died of other causes and gave no recognizable clinical evidence of hypoglycemia.

It is highly probable that in the 4 patients operated upon by resection of portions of the pancreas without conspicuous improvement in symptoms (Cases 2, 3, 4, 8) small adenomata in the remaining pancreas may well have been overlooked. When operation is done for hypoglycemia careful palpation and inspection of the body and tail of the pancreas is indicated to detect the comparatively small tumors that could account for the clinical symptoms. If such a search is fruitless it would appear necessary to mobilize the pancreas fairly completely and to remove at least

four fifths of the gland. Mobilization of the pancreas could be facilitated markedly by removing the spleen with it thus obviating the necessity of ligating the innumerable tributaries of the splenic artery and vein which course along the upper border of the pancreas.

SUMMARY

Hyperinsulinism with its resulting hypoglycemia produces symptoms of weakness verging on exhaustion, mental confusion, disorientation, epileptiform attacks, convulsive seizures, syncope, unconsciousness, coma and death. Clinically and anatomically it has been demonstrated in connection with carcinoma of the islands of Langerhans, adenoma of the islands of Langerhans, and hyperplasia of the pancreas. The last condition is still purely hypothetical and it may ultimately be found that the hypoglycemia in similar cases is dependent not upon simple hyperplasia of the gland but upon small adenomata embedded in the gland and therefore not easily demonstrable at operation. The presence of such small adenomata should, however, be carefully sought for in any case operated upon for spontaneous hypoglycemia before resorting to partial pancreatectomy. Case 3 is presented as the second instance of spontaneous hypoglycemia due presumably to simple hyperplasia of the pancreas, improved by partial resection of the pancreas.

THE INFLUENCE OF ENDOMETRIUM UPON THE RABBIT OVARY AFTER HYSTERECTOMY

J. VALTON SEASUMS, M.D. GALVESTON, TEXAS, AND DOUGLAS P. MURPHY M.D., F.A.C.S.
PHILADELPHIA, PENNSYLVANIA

From the Gynecology Hospital, Institute of Gynecologic Research, School of Medicine, University of Pennsylvania.

IT is a generally accepted clinical observation that hysterectomy even with the conservation of one or both ovaries hastens the onset of symptoms of the menopause. A second clinical observation is that these symptoms are less likely to develop if the amputation is performed high enough to insure the retention of sufficient endometrium to permit at least a scanty menstruation. These two observations have led to the theory that the endometrium produces a hormone essential to the normal functioning of the ovary; its removal disturbs the normal endocrine activity of the latter organ which dysfunction in turn is responsible for the early onset of the menopause. In the present experimental investigation, an attempt has been made to find out whether the endometrium is essential to the normal functioning of the ovary.

Dysfunction of the ovary following hysterectomy can be studied indirectly from the anatomical point of view. Little knowledge is available regarding the structure of the human ovary permitted to remain *in situ* for a considerable period of time following operation. Though such ovaries have been examined none has been studied in serial section consequently until an adequate number of these studies are made, the histological picture of the ovary after hysterectomy will be understood best by a study of serial sections of the animal ovary.

The present experimental investigation concerns the gross and microscopical structure of the rabbit ovary removed some months fol-

lowing hysterectomy and is based upon observations on 32 animals. Endometrium was autotransplanted in half of these at the time hysterectomy was performed.

The object of the study was to determine first if structural changes occur in the ovary of the rabbit as a result of hysterectomy second, if so their nature, and third whether loss of endometrium is a factor in bringing about these changes.

REVIEW OF LITERATURE

Human ovary after hysterectomy. Twenty two reports were studied which dealt with the condition of human ovaries removed some weeks, months or years following hysterectomy (1-5 7-14 17 21 23-26 31 33 35). Among the gross pathological changes, cysts were noted by ten observers and atrophy by five. These were the only gross findings common to any two reports. Eight of the 22 authors reported microscopic findings. Five of the 8 observed nothing abnormal (3 8 9 11, 17) of the other 3 Hawks and Vineberg observed cystic changes and Werth reported the presence of large follicles and the absence of ova.

These statistics are probably misleading with respect to the frequency with which abnormal developments occur in conserved ovaries, as obviously few ovaries which are normal and hence produce no trouble are removed at a second operation.

Animal ovary after hysterectomy. Of 19 studies dealing with the anatomy of the animal ovary 17 included microscopic examina-

tion In 6 of the 17 studies, the ovaries were described as being microscopically normal, in the remaining 11, alterations were observed Schubert saw no ova, Lindig observed dilated follicles, Terada found follicular atresia, Kettler and Jacobsohn noted a smaller number of follicles than normally while Loeb and Takakusu both described large corpora lutea, which were believed to have resulted from an inhibition of the regressive power of these bodies. Degenerative changes were observed in four experiments (18 22 33 34) but in only two were cysts found (19 27)

Human ovary after hysterectomy and uterine transplantation Three reports concerned the transplantation of human uteri or portions of endometrium at the time of hysterectomy, but gave no later description of the ovaries (28, 33 34)

Animal ovary after hysterectomy and uterine transplantation Four previous workers reported the results of their efforts to influence ovarian function experimentally by means of uterine transplantation Schubert transplanted the whole uterus of a goat with no resulting effect upon the estrous cycle Zimmernann (33, 34) transplanted pieces of endometrium into the abdominal wall in hysterectomized rabbits, and found that regressive changes in the retained ovary were inhibited as long as sufficient uterine tissue remained viable Takakusu transplanted portions of uterus into the abdominal wall of one series of rats at the time of hysterectomy, and of a second series of these animals 3 or 4 weeks after hysterectomy The ovaries of the group submitted to an immediate transplant were found subsequently to be more nearly normal in microscopical appearance, than those from the group submitted to transplantation 3 to 4 weeks after their hysterectomy was performed Parfenoff, using a single series of mice, found that hysterectomy without endometrial transplantation produced follicular atrophy With the use of endometrial transplants into the abdominal wall, he was able to stimulate the growth of new follicles and fresh corpora lutea.

EXPERIMENTS

Materials and methods Sixty-four adult rabbits (8 pregnant, 26 exhibiting varying

degrees of heat, and 30 not in heat), were subjected to hysterectomy, half of the group receiving, simultaneously, autotransplants of endometrium in the abdominal wall The operations were conducted under either ether inhalation anesthesia or following the intraperitoneal injection of a watery solution of "amytal" (iso-amyl-ethyl barbituric acid) In each instance, the entire uterus was removed, including the upper half of the vagina and the portion of each oviduct next to the uterus Three pieces of endometrium, approximately 3 to 4 millimeters in largest diameter, were then placed in a pocket in each rectus abdominis muscle During the operation, touching of the ovaries or traction on the mesovarium was avoided The animals were isolated during the period of wound healing after which they were herded together until sacrificed

During the interval between operation and sacrifice, no attempt was made to test ovarian function by the willingness of the female to accept the male. Since the rabbit ovulates only at the time of copulation or of other sexual excitement, as when one female in heat covers another, had copulation been permitted and had it occurred in some cases only, it would have injected a variation into the foliular picture presented by the entire group

Of the original 64 animals operated upon 52, divided equally between the transplant and the non transplant groups, lived 6 months All were killed by chloroform inhalation 30 at the end of 6 months, and 3 months later, or 9 months following hysterectomy, the 13 remaining were sacrificed The gross appearance of the ovaries and transplants was recorded and both were prepared for sectioning, Susa fixation being used For control purposes, ovaries were removed from 13 non hysterectomized adult rabbits which were definitely not in heat

RESULTS

Classification of ovaries The ovaries fell readily into 3 treatment groups Group I, ovaries from control animals (non-treatment group) Group II, ovaries from animals subjected to a simultaneous hysterectomy and autotransplantation of endometrium (trans-

TABLE 1—NUMBER OF SECONDARY FOLLICLES

	A 6	2.4	80	69
	A 4	3	61	41
	A	1.5	60	60
	Average	2.7	87	51

Showing: (a) the number of secondary follicles by actual count, 0.25 millimeter or more in diameter observed in (I) 5 control ovaries, (II) 5 ovaries from animals subjected 6 months previously to a simultaneous hysterectomy and autotransplantation of endometrium, and (III) 5 ovaries from animals subjected to hysterectomy without transplantation of endometrium, together with (b) the weights of the animals and (c) the weights of the ovaries which contained the counted follicles. Note that, on the average, the operated upon animals (Groups II and III) possessed fewer secondary follicles than the control animals (Group I) and that the animals subjected to a transplantation of endometrium (Group II) possessed a larger number of secondary follicles than the ones subjected to the hysterectomy without the transplantation of endometrium (Group III). Also observe that the average weights of the ovaries in the different groups did not vary proportionally with the number of follicles in the same groups.

plant group) Group III, ovaries from rabbits subjected to a hysterectomy without an autotransplantation of endometrium (non-transplant group)

Gross appearance of ovaries The ovaries of the 51 animals operated upon (Groups II and III) were in the resting state. Whether this uniform condition was a sequel of the hysterectomy or due to other circumstances, cannot be stated.

The ovaries of 49 of the 52 rabbits were grossly normal. The remaining animals ex-

hibited one normal and one abnormal ovary apiece. In each case, the latter ovary formed part of a mass composed chiefly of oviduct distended with clear fluid, apparently due to blocking of the uterine end by a ligature. In these three instances, the ovaries were thinned out and their outlines were very indefinite. In no case did the ovaries of the animals operated upon exhibit grossly either signs of atrophy or of cyst formation other than that mentioned above.

Twenty six ovaries from the non-treatment group (I), 50 from the transplant group (II) and 51 from the non-transplant group (III) were weighed and measured. There were no significant differences in the size or weight of any of these ovaries.

Gross appearance of transplants Each of the 36 animals which received autotransplants of endometrium when killed possessed at least one piece of engrafted tissue of considerable size. In 20 cases, bilateral transplants were present, in the remaining 6 only a single one. The transplants were multilocular cysts, the largest of which reached a diameter of 25 millimeters. In animals killed 6 months after operation the transplants were slightly larger on the average than those in animals killed 9 months after operation.

After they had remained in fixative for some time, the transplants were bisected. The majority contained clear fluid others possessed a yellow or white granular material and in one or two a gelatinous substance was present. One transplant from each of 20 of the animals was studied microscopically half of each one was cut serially in sections 6 micra thick and each fiftieth section was examined. These transplants were removed from the 20 animals whose ovaries were studied microscopically.

Microscopical appearance of transplants In 18 of the 20 transplants (Fig. 1), the cells lining the cysts varied in shape some were ciliated though the majority were not. Most of them were normal in appearance, only a few exhibited degeneration, which was extensive in only 2 cases. The degenerated cells desquamated and were found suspended in the liquor which filled the cyst cavities. In 2 cases the cells lining the cysts dipped into

the underlying tissue, forming structures similar to the small uterine glands (Fig 2)

The tunica propria, which was composed of a loose sheet of typical fibroblasts varied greatly in thickness. It was rich in blood vessels and poor in lymphocytes and leucocytes. Bundles of involuntary muscle fibers were characteristic of most of the transplants, in some cases forming a dense sheath.

Two of the 20 transplants were in the process of degeneration, in them the cyst cavity was narrow. The epithelial lining was almost absent, and the tunica propria also showed signs of degeneration. This was associated with hemorrhage and an invasion of leucocytes and lymphocytes.

Microscopic appearance of ovaries Microscopic study of the ovaries included (1) a count of the secondary follicles (those above 0.25 millimeter in diameter and with cavity formation), (2) measurement of the largest diameter of each, (3) an estimation of the number of primary follicles, (4) the frequency with which atresia occurred, and (5) the condition of the remaining tissues in the organ.

One ovary selected at random from each of 19 non-transplant, 20 transplant and 7 control animals, was cut parallel to its long axis, in serial sections 6 micra thick, which were stained with hematoxylin-eosin.

Number of secondary follicles The secondary follicles in 15 ovaries which included 5 from control animals and 10 from the transplant and the non-transplant groups were counted in the following manner. Each sixth section in its entirety, was projected on paper at a magnification of 20 diameters outlined in pencil, and each secondary follicle, with an outside diameter of 5 millimeters or more when projected, was also outlined. This minimum follicle size was selected arbitrarily in view of the difficulty of measuring accurately projected follicles of a lesser diameter. The first section of each follicle to appear was given an identification number, which it retained as its subsequent sections reappeared on other slides.

The number of these secondary follicles in the 15 ovaries, together with the weights of the animals and of the ovaries which contained the counted follicles, are recorded in

TABLE II—NUMBER OF SECONDARY FOLLICLES IN RABBIT OVARY AFTER HYSTERECTOMY

Treatment group	Group A			Group B	
	N. of animals	Follicles		N. of animal	Follicles
		Actual count	Average estimated ratio		Average estimated ratio
I Control	5	90.0	83.8	5	113.5
II Transplant	5	69.8	66.8	13	50.0
III Non-transplant	5	51.2	42.8	15	37.0

Showing the results of 3 methods for establishing the ratios between the number of secondary follicles (those with cavity formation) in one ovary from each of (I) 5 control animals, (II) 5 subjected to simultaneous hysterectomy and autotransplantation of endometrium, and (III) 5 subjected to hysterectomy without transplantation of endometrium. The average number of secondary follicles (.25 millimeter or more in diameter) by actual count is recorded for the 5 ovaries (Group A) in each of the three treatment groups and the average of the total number of sections of all follicles seen in each sixtieth section of each of the same ovaries is also shown (Group A). Contrasted with these, are the averages of the total number of sections of all follicles seen in each sixtieth section of 31 additional ovaries (Group B). Note that the averages of the estimated ratios between the numbers of sections of secondary follicles in Groups A and B in the three treatment groups are relatively consistent with the averages of the actual counts of the follicles in Group A.

Table I. The ovaries of the animals subjected to a simple hysterectomy (Table I, Group III), exhibited approximately half the number of follicles possessed by the control series (Table I, Group I), though the weights of the ovaries in these two groups were approximately the same. The ovaries of the transplant group (Table I, Group II) possessed a follicular count midway between those of the controls (Group I) and of the non-transplant animals (Group III). Significant differences seemed to exist between the actual number of secondary follicles in these three groups of ovaries as shown numerically in Table I and graphically in Figure 3.

The relative number of secondary follicles in the three treatment groups was arrived at in another manner. The number of sections of secondary follicles present in each sixtieth section of each of the 15 ovaries was counted. The total of these sections in all of the sixtieth sections of each ovary gave a relative figure but not an absolute one, for the number of follicles present. The average of these estimations for the 3 treatment groups of ovaries

TABLE III.—NUMBER OF NORMAL PRIMARY FOLLICLES AND ATRETIC PRIMARY AND SECONDARY FOLLICLES

Condition of follicles	Ovaries showing many follicles		
	7 control Per cent	19 non-transplant Per cent	20 trans- plant Per cent
Normal	100	63	46
Atretic	100	35	54

Showing the estimated relative number of (a) normal primary follicles and (b) atretic primary and secondary follicles in one ovary from each of (1) 7 control animals, (2) 19 animals subjected to a hysterectomy 6 months previously and (3) 20 animals subjected to a simultaneous hysterectomy and autotransplantation of endometrium, also 6 months previously. The number of normal and atretic follicles is expressed as the percentages of the number of ovaries which possessed many as compared with few of these follicles, on the basis that 100 per cent of the control ovaries possessed many normal primary follicles, and many atretic primary and secondary follicles. Note the decreased percentages of ovaries of the two groups operated upon which possessed many normal primary follicles and the increased percentages of ovaries in both groups operated upon, which exhibited many atretic follicles. In other words, the animals operated upon possessed fewer normal primary follicles and more atretic primary and secondary follicles than did the ovaries of the control animals.

is recorded in Table II. The ratio between these estimated averages (Table II Group A) was found to be consistent with the ratios observed between the actual counts of the follicles in the same ovaries (Table II Group A). Since this shorter method of estimating the relative number of follicles in the 3 treatment groups gave results which were consistent with those secured by actual count, it was used in determining the relative number of follicles in the ovaries of 31 additional rabbits (Table II Group B). The constant relation between the actual count of the follicles in Group A, and the estimations of their numbers in Groups A and B emphasizes the constancy of the differences in the numbers of follicles in the control, transplant and non transplant groups.

Size of secondary follicles. The size of each secondary follicle in the 15 ovaries (Table I and Table II Group A) was recorded in terms of its maximum diameter. It was found that the follicles in the ovaries of both groups of animals operated upon reached the same ultimate size as did those in the control group

From this observation it is concluded that growth of the measured secondary follicles, in the ovaries of animals operated upon, was not interfered with by removal of their uteri. This fact is of interest in view of the small number of follicles found after hysterectomy.

Number of primary follicles. The number of primary follicles was not counted but only estimated. The ovaries of the control animals possessed either a continuous layer of primary follicles in the cortex or occasional interruptions in this layer of follicles, which were also noted in the ovaries of some of the animals operated upon. Such ovaries were described as possessing many primary follicles. In case larger gaps existed in the layer of primary follicles in the ovaries of animals operated upon or if the follicles appeared only in scattered groups, these ovaries were described as possessing few follicles.

Comparing the percentages of ovaries in the three treatment groups which presented many in contrast to few normal primary follicles (Table III) it becomes evident that in the 2 groups operated upon (II and III) there were fewer ovaries containing many primary follicles. In other words, the ovaries of the animals operated upon (Groups II and III) possessed fewer primary follicles than did those of the control animals (Group I). The question whether this marked difference was due (1) to failure of the primary follicles to form or (2) to the early degeneration of a large number of them will be discussed later.

Atresia. The ovaries of control and operated upon animals possessed varying numbers of atretic primary and secondary follicles. These were not counted but only estimated. Where they were more numerous, the term many atretic follicles was used where less frequent, the term few. The number of ovaries (expressed in percentages) of animals operated upon which exhibited many atretic primary and secondary follicles is recorded in Table III on the basis that 100 per cent of the control ovaries possessed many of these follicles. It will be noted that atresia was observed more frequently in the ovaries of the animals operated upon than in the controls and also that transplantation of endometrium appeared to lessen the amount of atresia.

TABLE IV—AMOUNT OF STROMA

Stroma	Ovaries		
	7 control Per cent	19 non-transplant Per cent	30 trans- plant Per cent
Well developed	100	13	25

Showing the frequency with which well developed stroma was observed in one ovary from each of (1) 7 control rabbits, (2) 19 subjected to a hysterectomy 6 months previously and (3) 30 animals subjected to a simultaneous hysterectomy and autotransplantation of endometrium also 6 months before. The amount of stroma is expressed as the percentage of ovaries which possessed a well developed stroma, as compared with those which had a poorly developed stroma on the basis that 100 per cent of the control ovaries possessed a well developed stroma. It will be noted that more of the ovaries of the 30 animals subjected to a simultaneous hysterectomy and autotransplantation of endometrium exhibited well developed stroma than did the ovaries of the 19 animals subjected to hysterectomy without autotransplantation of endometrium.

Germinal epithelium The histological picture of the germinal epithelium of the groups operated upon was identical with that of the controls.

Stroma In the ovaries of the control animals, the amount of stroma its distribution and structure, with one exception were found to be uniform (well developed). The larger blood vessels were surrounded with abundant connective tissue, which followed the smaller ones into the cortex and distinct septa of connective tissue were present between the different sized groups of interstitial cells.

In the exception just mentioned the connective tissue formed a sheath of only medium thickness around the larger vessels and the septa between the groups of interstitial cells were also more delicate. The term "moderately developed" stroma was applied to this case. This type of stroma was observed in quite a large number of the ovaries of the animals operated upon. In the cases in which the connective tissue septa in some ovaries were almost entirely absent, and the vessels were surrounded with only a thin layer of connective tissue the stroma was termed poorly developed.

The number of ovaries (expressed in percentages) in the different groups, which possessed a well developed stroma is shown in Table IV. These figures are based on the finding that 100 per cent of the control ovaries

TABLE V—AMOUNT OF INTERSTITIAL TISSUE

Amount of Interstitial tissue	Ovaries		
	7 control Per cent	19 non-transplant Per cent	30 trans- plant Per cent
Much	100	107	90

Showing the estimated amount of interstitial tissue in one ovary from each of (1) 7 control animals, (2) 19 animals subjected to a hysterectomy 6 months previously and (3) 30 animals subjected to a simultaneous hysterectomy and an autotransplantation of endometrium also 6 months previously.

The amount of interstitial tissue is expressed as the percentage of ovaries which possessed much tissue in contrast to the percentage which possessed a moderate amount, on the basis that 100 per cent of the control ovaries possessed much interstitial tissue. Note that the ovaries of the 3 groups of operated upon animals possessed approximately the same amount of interstitial tissue as those of the control animals.

possessed a well developed stroma. It is evident (1) that more control animals exhibited a well developed stroma than did the animals operated upon and (2) that the stroma was better developed in the ovaries of the transplant group than in those of the non transplant group.

Interstitial tissue The amount of interstitial tissue was found to be approximately the same in the ovaries of control animals and animals operated upon (Table V). The interstitial cells, however, varied in size, shape, and structure. Four types connected with transitional forms were observed (Table VI).

Type I This cell small, polygonal in shape, its nucleus about the size of a red corpuscle, was surrounded with a narrow layer of cytoplasm, which was usually shrunken. If properly preserved and stained, it was slightly granular and neutral in its reaction to the stains.

Type II The nucleus of this type of cell was polygonal and slightly larger than that of Type I, its cytoplasm was abundant and contained granules which showed a strong affinity for the acid dye. It contained vacuoles of varying sizes, the largest sometimes the size of its nucleus.

Type III The cells of this type resembled those of Type II. However, the individual cell and its vacuoles were considerably larger than those of Type II.

TABLE VI—TYPES OF INTERSTITIAL CELLS

Cells	Ovaries		
	7 control Per cent	20 non- transplant Per cent	20 trans- plant Per cent
Type I Follicular, or equal to Type II	00		45
Type II Follicular, or equal to Type I	00	45	4
Type III Max Abn 1	7 00	4	16
Type IV Max Abn 2			5

Showing the frequency with which four types of interstitial cells were observed in one ovary from each of (1) 7 control rabbits, 2) 20 animals subjected to a hysterectomy 6 months previously, and (3) 20 animals which at the same time were subjected to simultaneous hysterectomy and autotransplantation of endometrium. The number of cells of each type is expressed as the percentage of ovaries which possessed the type of cells recorded in the left column, on the basis that 100 per cent of the control ovaries possessed approximately equal numbers of cells of Types I and II. Note that both groups of animals operated upon possessed fewer of the cells of Types I and II, and that the cells of Type I were seen more frequently in the ovaries of the transplant group than in those of the non-transplant group.

Type II These cells looked like fat cells. They were large round and contained a few large vacuoles or perhaps only one and some remnants of granular cytoplasm.

In spite of these dissimilarities, these four types of cell appear to be true interstitial cells. Their differences might be explained on one of two assumptions. Either they represent cells which are functioning differently or they are steps in a slow but progressive form of degeneration.

DEDUCTIONS FROM EXPERIMENTS

Although scattered data have appeared in the literature concerning the influence of hysterectomy (upon both humans and animals) in producing cysts in ovaries which have been left *in situ* following this operation, our large number of experiments gave no evidence that this is so in the case of the rabbit. From our observations we conclude that loss of endometrium plays no rôle in the production of ovarian cysts in the rabbit.

Endometrial autotransplants appear to grow readily for a short time in the abdominal

wall of the rabbit. Ultimately, however they lose their typical structure, and become cystic. In view of the several histological differences between the ovaries of the animals which received transplants and those which did not, it would appear that the transplants functioned for a while at least. In this connection it must be remembered that transplanted endometrium even if entirely healthy is less in amount than in the normal animal. Consequently if inhibiting or degenerative changes in ovaries result from removal of all endometrium, these same changes, to a lesser extent, might be expected in all transplant cases, especially in those in which the transplant failed to grow or later atrophied.

It is also quite likely that the endometrium left after high amputation of the human uterus is less subject to degenerative changes than that transplanted into the rectus muscle of the rabbit. Obviously then, the ovaries remaining in the human being which retained high cervical endometrium would be less likely to exhibit inhibiting or degenerative changes than would those in animals whose only endometrial tissue was in the rectus muscle.

The decreased number of primary and secondary follicles observed in the two groups of operated upon animals raises the question of the manner in which these decreases were brought about. It is possible that the reduction in the number was due to (1) an inhibition of formation of new follicles, or (2) a degeneration of existing follicles, or (3) a combination of the two. The small number of primary follicles in the cortex of the ovaries of the animals operated upon suggests that fewer of them formed than normally while the increased number of atretic primary and early secondary follicles indicates that many follicles failed to develop normally. Atresia of primary and of small secondary follicles was more frequent than in the case of the larger secondary follicles. In view of these observations, and because the larger follicles of control animals and those operated upon all reached the same ultimate size, it would seem that the hysterectomy influenced chiefly the primary and the smaller secondary follicles, and that it acted mainly by inhibiting the formation of new

Fig. 1. Showing wall of typical endometrial cyst resulting from autotransplantation of endometrium into rectus abdominis muscle of rabbit when hysterectomy was performed 6 months previously. A Epithelial lining of cyst B tunica propria containing several gland like structures C smooth muscle fibers, probably uterine in origin D cyst capsule E rectus abdominis muscle. $\times 75$

follicles since the absence of primary follicles in the cortex was more evident in most of the ovaries than was the presence of an undue amount of atresia.

The germinal epithelium presented nothing unusual from the anatomical point of view. The significant decrease in the estimated number of primary follicles in the ovaries of the animals operated upon and the actual decrease (40 per cent) in the number of counted secondary follicles however suggests that the operation must have influenced this tissue functionally even if there was no observable anatomical alteration.

No evidence from the experience of others has been found which indicates that the stroma of the ovary is influenced by the action of any hormone, or that the connective tissue of any other organ is similarly affected (6). On the contrary, our findings point to (1) a definite difference in the amounts of stroma in operated upon and control animals, and (2) a difference in the amount of stroma in the transplant group as compared with the non transplant group. From these observations it might be concluded that the stroma is influenced by loss of the uterus and therefore that it is affected by hormones.

The interstitial tissue appeared to be constant in amount in the ovaries of both the operated upon and the control animals. Its amount therefore, does not seem to have any

Fig. 2. Showing an endometrium-like structure which projected into the cavity of a cyst, resulting from the autotransplantation of endometrium into the rectus abdominis muscle of a rabbit when hysterectomy was performed 6 months previously. Note the ciliated epithelium on the surface and beneath it the numerous endometrium like glandular structures.

direct or appreciable relation to loss of endometrium.

In the control ovaries the more normal types of cells (I and II) predominated (Table VI), and though those of Type III were seen, the cells of Type IV were absent. In the ovaries of the non transplant group, the Type II cells were observed more frequently than in the transplant group. This indicates a shifting from the normal type of cell, following hysterectomy to that of the cell which was either functionally different or degenerating according to the interpretation of the change. Since the cells of Type I were found more frequently in the transplant group than in the non transplant group the conclusion may be drawn that the presence of the transplant tended to check the shifting process from Type I toward IV. The reason for this difference cannot be stated though it might be assumed that the presence of the endometrium was a factor.

The arrangement of the cells of Type III in clusters of various sizes, suggests that these cells might have been mistaken by other observers for degenerating corpora lutea. How

SUMMARY

1 Observations are recorded upon (a) the gross and microscopical appearance of the ovaries of 26 rabbits which were subjected to a hysterectomy 6 months or more previously and upon (b) 26 which were subjected to a simultaneous hysterectomy and autotransplantation of endometrium.

2 The ovaries of both groups of hysterectomized animals exhibited grossly no significant differences from the ovaries of control (unoperated upon) animals, except that none of them showed any signs of follicular activity characteristic of estrus.

3 Microscopically the ovaries of the hysterectomized animals differed from those of control (unoperated upon) animals by possessing (a) fewer primary and secondary follicles (b) more atretic follicles, chiefly primary (c) less stroma (d) more atypical interstitial cells.

4 In comparison with the ovaries of the animals subjected solely to a hysterectomy the ovaries of animals subjected to a simultaneous hysterectomy and autotransplantation of endometrium microscopically exhibited (a) more secondary follicles (b) fewer atretic follicles, (c) more stroma (d) a healthier type of interstitial tissue.

CONCLUSIONS

1 Hysterectomy upon the rabbit (a) inhibits the development of estrus and (b) brings about changes in the microscopic structure of the remaining ovaries which tend to be both inhibitory and degenerative in nature.

2 Autotransplantation of endometrium has a tendency to limit the extent of the inhibitory and degenerative changes which result from hysterectomy.

3 Evidence is brought forward to support the theory that the endometrium elaborates a hormone which influences the ovary.

The authors are greatly indebted to Dr. George S. de Knyf, of the Department of Anatomy for continued assistance throughout the period of the study.

Fig. 1. Shows the relative number of secondary follicles (those with antral formation) seen in A, the ovary of an adult rabbit in the resting stage; B, an ovary removed 6 months after a simultaneous hysterectomy and autotransplantation of endometrium; and C, an ovary removed after a hysterectomy without transplantation of endometrium. Note that the ovary from the animal subjected to a hysterectomy and an autotransplantation of endometrium, B, possessed more secondary follicles than the ovary from the animal subjected to a hysterectomy without transplantation of endometrium, C, and that both of these ovaries possessed fewer secondary follicles than the control ovary A.

ever a careful search of all our material failed to disclose any remnant of a single corpus luteum.

The operation of hysterectomy appeared to have a definite influence upon the ability of the rabbit to exhibit heat. More than half of the hysterectomized animals at the time of operation were either pregnant (8) or exhibited moderate degrees of uterine turgescence (26). Following the period of wound healing the entire group was herded together yet in spite of this opportunity which was offered for the covering of one female by another no remnants of corpora lutea were observed in any ovary to indicate that a pseudo-pregnancy had occurred and therefore that estrus existed.

THE RELATION OF PULMONARY TUBERCULOSIS TO ANORECTAL FISTULÆ

A CLINICAL, PATHOLOGICAL AND BACTERIOLOGICAL STUDY

A. J. CHISHOLM, M.D., F.A.C.S., DENVER, COLORADO

From the Research Department, National Jewish Hospital

Clinical interpretation it is common experience that views change as more accurate and detailed scientific observations serve as a basis for a clearer insight into the actual conditions present. Medical history is replete with interpretations and discussions on anorectal fistulæ and the literature on this subject alone has assumed voluminous proportions. Several decades ago discussion centered about the question whether all anorectal fistulæ were of tuberculous origin or not, and proponents of either view were easily found. With the introduction of better scientific methods, agreement was more common and discussion was relegated mainly to an explanation of the origin of the condition which probably will never entirely be settled and which so far as practice is concerned is of little actual importance. In the discussions of anorectal fistulæ over the decades, there is to be noted also the influence of changed conceptions regarding tuberculosis in general and in this appears the controversy of aerogenic versus intestinal infection, and local versus hæmatogenous and lymphatic infection. Thus, historically Lockhart Mummery in 1909 advises us "The operation for fistula-ano is associated with the very earliest records of surgical literature. In the days of early civilization when cleanliness was a matter of secondary consideration—water being used chiefly for drinking purposes—and the horse was the only means of transport fistula must have been even a more serious inconvenience than it is now. In looking up the records of St. Mark's Hospital, he found that since the year 1909 the number of cases of fistula has steadily diminished. The number in 1926 being a little over one-half the number admitted in 1909—a fact which is easily understood in the light of increasing sanitary hygiene. Regarding the primary cause he cites abscess in the tissues surrounding the

rectum and classifies the causes as follows: (1) congenital cysts (2) foreign bodies (3) fissures or ulcers (4) suppuration of the intramuscular glands, and (5) tubercle. Regarding the bacteriology he states "Apart from tubercle the nature of the infective organisms is probably not important. The pus from most fistulæ on culture shows a very mixed infection." Regarding the diagnosis of tuberculous fistulæ he states "Such fistulæ (tuberculous) can generally be diagnosed from the appearance of the parts but this is not entirely reliable. Examination of the pus or discharges for tubercle is quite useless. Histological examination of a few pieces of the wall of the fistula is fairly reliable but the only certain method is by inoculation into guinea pigs after concentration with anti-formin.

Reviewing the current German views on the etiology of rectal fistulæ, Thoms in 1920 cites Richard Volkmann and Franz Koenig as believing rectal fistulæ to be of tuberculous origin in the majority of cases while De Quervain considers at least half of them to be tuberculous, and Melchior in 1910 cites an incidence of 61 per cent, and Goetz reports 45 per cent in Munich. Opposing these views are those of Lanz who considers tuberculosis of little significance, those of Frey (1914) who found only 6.9 per cent to be tuberculous by macroscopic and microscopic examination of 72 patients operated upon. Frey insists that only the findings at the fistulous site are significant and the presence of tuberculosis elsewhere is not conclusive, while Melchior contends that even a negative microscopic examination cannot exclude the presence of tuberculosis in the fistulæ. The futility of arriving at conclusions from the methods used at that time is noted from this article.

In 1925 Fansler read one of his first contributions on the relationship of tuberculosis

Fig. 1. Typical acute inflammatory (granulocytic) reaction in specimen from Case 137 found negative for tubercle bacilli by bacteriological examination. Left low power, right, high power

Fig. 2. Two examples of scar tissue (fibroblastic reaction) in bacteriologically negative cases for tubercle bacilli, left, Case 113, and right, Case 139.

to fistula in-ano before the American Medical Association. After reviewing the literature he asks six questions: (1) What constitutes a tuberculous fistula and on what findings are we justified in making the diagnosis? (2) What percentage of fistulæ are tuberculous? (3) In what percentage of cases is the tubercu-

lous fistula the primary lesion and in how many cases is it merely a secondary infection from a focus elsewhere in the body? (4) What percentage of fistulæ occurring in tuberculous patients are tuberculous? (5) Does pulmonary tuberculosis have a tendency to cause fistula in ano? and, (6) Do simple fistulæ

Fig 3. Two examples of mild chronic inflammatory tissue reaction. One from a specimen bacteriologically negative for tubercle bacilli left, Case 15 and the other bacteriologically positive for tubercle bacilli, right, Case 121.

occurring in non tuberculous persons indicate that the person has a tuberculous tendency. His answers, indecisively given are based partly on his personal experiences but mainly on conceptions formed from the studies of others. He sums up his beliefs as follows

Fig 4. A typical granulomatous tissue with monocytes and epithelioid cells in a specimen bacteriologically negative for tubercle bacilli, Case 104.

"(1) We are not justified in making the diagnosis of tuberculous fistula except by definite microscopic picture or in cases in which the lesion has the typical appearance (2) Considering all cases of fistula in ano it is doubtful whether more than 2 or 3 per cent are tuberculous in character (3) Tuberculosis is very rarely primary in fistula in ano (4) Probably 25 per cent of fistulae occurring in tuberculous patients are tuberculous 0.33 per cent of tuberculous patients also have tuberculous fistulae (5) In view of the ease with which the tubercle bacillus affects the mucous membrane of the bowel it would seem possible that in some cases at least in some persons, in whom the fistula appear to be a simple inflammatory process, the original lesion in the bowel wall is due to the tubercle bacilli. However this is purely a matter of opinion and has not been proved (6) It is probable that tuberculosis as such has a tendency toward the formation of rectal fistula, and (7) it would seem that the formation of rectal fistulae in persons who are under weight is undoubtedly a warning of the presence of pulmonary tuberculosis or of a tendency toward its development

In 1930 and 1931 Petter and Fansler conclude from personal observations reported

Fig. 5. Giant cells in a specimen from Case 35 bacteriologically negative for tubercle bacilli. Left, low power right high power

from Glen Lake Sanatorium that tuberculous lesions about the anus and rectum occur secondary to a focus elsewhere in practically every case and that perirectal abscess and fistula in ano in the tuberculous patient present a typical history and clinical picture. They found perianal tuberculous skin lesions in 0.8 per cent of patients observed while perirectal abscess and fistula, in the same group, occurred in 5.8 per cent.

A study of 101 cases of abscess and fistula brought out several important facts, the 'proof of tuberculosis' is often quite a task. Smears of exudate are not reliable nor are guinea pigs inoculated with the exudate wholly dependable. A combination of three laboratory procedures gives a reliable 'proof of tuberculosis' (1) exudate in guinea pig (2) macerated tissue in guinea pig and (3) tissue section. Frequently tissue section will show a histological picture of chronic inflammation, but not tubercle formation and a piece of the same tissue injected into the guinea pig will show definite evidence of tuberculosis.

In 1926 Leslie following a careful study of the literature concludes that there is still no uniformity of opinion as to the etiological importance of the tubercle bacillus in ischio-

rectal abscess and fistula in ano and suggests that all abscesses and fistulae in large hospital services be submitted to the following tests (a) guinea pig inoculation of material from all specimens, (b) a histological study of sections from all cases, (c) a comparative study, following definite diagnosis, of the after history

Fig. 6. Giant cell in a specimen from Case 110 bacteriologically negative for tubercle bacilli.

Fig. 7. Giant cells in a specimen from Case 60 bacteriologically positive for tubercle bacilli.

of all cases treated and (d) more complete examination for tuberculous foci elsewhere.

The same year Clarke of Belfast reported his observations on patients with 109 cases of fistula having pulmonary tuberculosis at the Foster Green Hospital for Consumptives and Chest Diseases from which he drew the follow-

ing conclusions. Ischio-rectal abscess and fistula in-ano occur in males about eight times more commonly than in females—about 5 per cent of male cases of pulmonary tuberculosis are associated at some time with an ischio-rectal abscess or a chronic fistula. The fistula or abscess may precede the signs in the lungs by years; there is evidence that 61 per cent of cases of fistula subsequently develop pulmonary tuberculosis; there is evidence that fistula occurs 13 times more commonly in tuberculous males than in non-tuberculous males.

As a result of a study of 150 cases of fistula in-ano Tung reported in 1927 that the condition affects people of all classes in China, and that hemorrhoids and tuberculosis were especially noted in the histories. In 100 cases the specimens were examined microscopically and 26 or 25.5 per cent proved to be tuberculous.

Two important communications have been presented from St. Mark's Hospital which merit citation here. The one was an anatomical study in 1929 by Naunton Morgan who analyzed 100 cases of peri-ano-rectal infections and found that fistula is three times more common in men than in women. Of 106 new cases of fistula during 1928, 146 were men.

Fig. 8. Classical small tubercle and giant cells in a specimen from Case 52 bacteriologically positive for tubercle bacilli. Left, low power magnification; right, high power showing cells and two typical giant cells.

Anorectal infection was much more common after the age of 30 years, the age of greater frequency being from 30 to 40, the incidence gradually falling off until the age of 60. The condition is more common in children between the ages of 10 and 15 than between the age of 15 and 20. Most fistulæ pass radially into the bowel (46 per cent). Of these more than half are situated in front of a line drawn transversely through the anus (54 per cent). More than half of the ischiorectal abscesses communicate with the bowel and are—or will become—complete fistulæ (56 per cent). A tuberculous fistula will heal well and rapidly, if the patient's general condition is good and there are no signs of active pulmonary disease. Fistula appears to be complicated by pulmonary tuberculosis more frequently in patients over the age of 40 years. In over 60 per cent of the cases there was no definite cause found for the infection, foreign bodies were found in 4 per cent, hæmorrhoids were present in 8 per cent, fissure was present in 7 per cent, inflammation of a crypt was present in 10 per cent. The initial lesion is probably microscopic and is overlooked.

The second and a most important study from St. Mark's which should be considered here, was reported in 1921 by Gabriel and has been frequently and repeatedly cited probably because it is the only detailed bacteriological and histological study of any extent performed to the present time in order to determine the percentage of rectal fistulæ that are tuberculous, the proof required being the definite demonstration or isolation of the tubercle bacillus. The cases investigated were not picked but were taken in succession as admitted into St. Mark's Hospital for operation. Cases of perianal abscess were included after discovering the futility of examining the discharge from tuberculous fistulæ in stained films, animal inoculation and histological methods were resorted to. In 30 of the 75 cases guinea pigs were inoculated. Pus scrapings, and granulation tissue were treated with an equal volume of 15 per cent anti-formin after being ground with fine quartz sand and after being diluted with 10 to 20 cubic centimeters of normal saline solution the sand and larger particles of tissue being

allowed to settle, and finally the supernatant fluid being used for anti-formin treatment. The anti-formin is allowed to act for 5 minutes with constant shaking the sediment then obtained by centrifuging is washed with saline and is then injected into the abdominal wall of a guinea pig. After inoculation the animal is kept alive for at least 6 weeks. The anti-formin sediment is also examined in smear for bacilli.

Histological examination of the tissue was performed on all of the 75 cases examined formalin fixation being used for this purpose paraffin embedding and hamatoxylin and eosin staining for cellular pathology and cold carbol-fuchsin staining with methylene blue counterstaining for tubercle bacilli. Of the 30 cases studied by guinea pig inoculation 6 or 20 per cent, proved positive for tuberculosis the ages ranging from 21 to 62 years. 5 specimens being from males and 4 of the 6 showed giant cells in sections while tubercle bacilli were found in none of the stained sections. The 24 negative cases were clinically simple with one exception a man aged 35 years who had evidence of pulmonary tuberculosis involving both apices with tubercle bacilli in the sputum. Section from the granulation tissue of the fistula was negative also. Giant cells were found in sections in 2 of the 24 negative cases by inoculation.

In the 45 cases examined only by histological methods, tubercle bacilli were found in the stained sections of 4 (9 per cent) and all revealed characteristic giant cells. Two of these were from men (39 and 49 years of age) with no evident phthisis or pulmonary infection, while the 2 other men (both 18 years of age) had definite pulmonary tuberculosis. One case showed large numbers of giant cells (considered foreign body giant cells) but no bacilli, while of the 40 remaining cases 2 fistulæ were suspicious and showed giant cells but no bacilli. Thirty-eight proved clinically simple, and in 6 of these a few giant cells were found but were considered of no significance by Gabriel, thus leaving finally 32 of the 45 without significant findings for tuberculosis as usually considered. In concluding Gabriel brings out a few additional points not mentioned above but worth considering. If

histological examination only is carried out and if no tubercle bacilli are found in sections a consideration of giant cells can only give a presumptive diagnosis the absence of giant cells does not exclude the possibility of the tissue being tuberculous.

From a survey of the literature on anorectal fistulae it may be questioned whether practically the classification pathology or treatment of this condition bears any significance to the bacteriological phases of the condition as is evident from a recent article on this subject by Miles. But a better understanding of the bacteriology and pathology of the condition must inevitably influence the clinician and surgeon's viewpoint as well as that of all those concerned with the health of man and may eventually entirely change our method of approach in dealing with the condition of anorectal fistulae.

Since the investigations of the past decade have given us a better insight into the interpretation of tuberculosis and especially has resulted in crystallizing our conceptions regarding the quantitative relations between a positive finding for acid fast bacilli in a smear or section examined microscopically and a positive finding bacteriologically by culture or guinea pig inoculation for tubercle bacilli as contrasted to acid fast bacilli and since we are better able today to interpret the pathological findings from a practical standpoint as well as quantitative standpoint it appeared desirable to study more extensively and more accurately the relation of anorectal fistulae to pulmonary tuberculosis. In initiating this work there were recognized a number of inherent weaknesses in methods available for the so called diagnosis of tuberculosis.

Any method used has its limitations, and these must be fully recognized in interpreting the findings with a certain method. Thus, the finding of acid fast bacilli in a smear or section with the microscope indicates that there are present in the material about 100,000 bacilli per cubic centimeter while the guinea pig or culture are able to discern as few as 10 to 100 bacilli of a virulent strain of human or bovine tubercle bacilli. The guinea pig or culture when properly used discern only tubercle bacilli and eliminate the saprophytic acid fast

bacilli. A precaution in using guinea pigs is to exclude the possibility of spontaneous tuberculous infection which may lead to erroneous conclusions. The quantitative differences between the findings with the smear or section examined microscopically as compared to the guinea pig or culture are particularly significant when we consider that few bacilli can still produce disease and that the reaction may not be of a specific character. It must also be recognized that cellular reactions are significantly non-specific in character and that even the classical giant cell can be produced by a foreign body or by micro-organisms other than tubercle bacilli and finally tuberculosis can exist without characteristic giant cell formation or tissue reaction and that reactions to the tubercle bacillus are possible, running the entire range from an acute purulent reaction to the formation of dense scar tissue. Add to this the fact that sections, unless serial which is beyond practical consideration, can only picture the reaction of a very small portion of a diseased tissue and may range from normal tissue to a profound grade of pathology dependent almost entirely on chance.

However since only a limited series of cases was studied by Gabriel, and since the past 10 years have given us better methods of bacteriological diagnosis and most of all have given us a better conception of tuberculosis it was decided to examine pus, scrapings and tissues removed from fistulae in ano at operation using every precaution to avoid extraneous contamination and to utilize for examination histological and bacteriological methods and to obtain accurate clinical records regarding especially the status of the patient as concerned tuberculosis. The guinea pigs used in these tests were specially raised for this purpose with all precautions taken to avoid spontaneous tuberculous infection. The culture method used was that previously described from the Research Department of the National Jewish Hospital (3) the oxalic acid crystal violet potato cylinder method. Smears were stained by the usual Ziehl-Neelsen steaming carbolfuchsin methylene blue method while sections were fixed with Zenker's solution paraffin embedded and were

stained with either hamatoxylin and eosin for cellular study or with carbolfuchsin and methylene blue for acid fast bacilli. Since there is nothing unusual about the methods which have been used except what has been previously recorded for isolating tubercle bacilli the details will be omitted from this paper so that the pertinent clinical data and histological and bacteriological findings may be presented.

A total of 155 cases were studied in this series 106 being negative clinically and roentgenologically for evidence of tuberculosis, 18 presenting evidences of arrested pulmonary tuberculosis and 31 being active cases of pulmonary tuberculosis. None of the cases of pulmonary tuberculosis could be considered to be of the advanced hopeless or fatal military type at the time the specimen was obtained for examination. The term active is not intended to convey a last stage case in this sense but rather to indicate the usual clinical interpretations of activity including physical and roentgenological findings of activity, pyrexia, etc.

In order to evaluate the results of the histological findings they were graded according to the results of an examination of several sections usually taken at several layers in the block of tissue utilized for this purpose. A compromise had to be struck in the case of certain tissues and they are usually recorded according to the findings of more pronounced grade and pointing to the more marked changes toward a tuberculous tissue. Normal tissues were graded as being negative — "0" tissues presenting evidences of acute or sub-acute inflammatory reactions with a pre-dominance of polymorphonuclear leucocytes or granulocytes were graded as "? tissues presenting evidences of a chronic inflammatory reaction with scar tissue (connective tissue formation) as the more marked change were graded as \pm ", tissues presenting granulomatous changes with the various types of monocytes, clasmatoocytes or histiocytes with epithelioid cells and lymphocytes but no

TABLE I—BACTERIOLOGICAL AND HISTOLOGICAL FINDINGS IN THIRTY-ONE CASES OF ACTIVE PULMONARY TUBERCULOSIS WITH ISCHIORECTAL ABSCESES OR ANORECTAL FISTULÆ*

In the majority of the cases the pulmonary tuberculosis was moderate (M. A.) or far advanced (F. A.). Most of the patients had anorectal fistulae.

* Acid fast bacilli were not found in any of the sections stained with carbolfuchsin for this purpose in this series of cases.

— means negative; ? means acute cellular reaction; + means acute tissue; ++ means granulomatous tissue; and +++ means tubercle or giant cells.

* Acid fast bacilli were not found in any of the sections stained with carbol-fuchsin for this purpose in this series of cases.

typical giant cells were graded '+' while tissues containing typical tubercles and giant cells in any part of the section were graded '++'. It must always be remembered however in evaluating such tissue findings that tubercle bacilli can under certain conditions produce typical acute cellular reactions with a predominance of polymorphonuclear

leucocytes or granulocytes and that a typical solitary tubercle sectioned in different places can reveal a variegated picture. These facts combined with the additional fact that giant cells can form around foreign bodies including cellular debris make a diagnosis based on tissue findings alone of uncertain value. All the tissues from the 155 cases were examined for acid fast bacilli after staining with carbol fuchsin but in none were they found in spite of the fact that those presenting the classical tissue picture for tuberculosis were carefully examined although it must be admitted that none of these with giant cells presented profound tuberculous changes with numerous giant cells, such as were described by Gabriel. In the total of 49 cases with active and arrested pulmonary tuberculosis in this series, only 4 presented giant cells and in only 2 of these were they at all fairly numerous. In recording the bacteriological findings, the sum of the culture and guinea pig findings is recorded which in most instances were in accord.

The results of these studies are recorded in Table I for the active cases of pulmonary tuberculosis, in Table II for the arrested cases of pulmonary tuberculosis, and in Table III for the non-tuberculous cases.

An examination of the data recorded in Table I reveals that of the 31 ischio-rectal abscesses or anorectal fistulae occurring in cases of active pulmonary tuberculosis there were 24 specimens in which tubercle bacilli were found by guinea pig inoculation and culture methods while only one (Case 90) revealed tubercle formation or giant cells, another (Case 60) a granulomatous tissue reaction and in none was acid fast bacilli found in sections of the tissues removed or in smears from the pus obtained from the abscess or fistula.

An examination of the findings recorded in Table II indicates that among 18 inactive cases of pulmonary tuberculosis with ischio-rectal abscesses or anorectal fistulae, there were found 10 cases in which tubercle bacilli were present as determined by bacteriological means (guinea pig and culture test) while only 3 of the 18 (which were also included among the 10 positive by bacteriological methods) revealed tubercle formation or giant cells [in

sections and another one, also among the 10 positive bacteriologically, presented granulomatous tissue changes but none was found to contain acid fast bacilli in sections or in smears from the pus obtained from the abscess or fistula.

Now if the bacteriological findings in the inactive arrested cases of pulmonary tuberculosis are compared with those for the active cases it is noted that 77 per cent of the active cases were found positive for tubercle bacilli by guinea pig and culture as compared to 55 per cent of the inactive arrested cases of pulmonary tuberculosis. Whether any great significance can be attached to the histological findings obtained in this study in view of all the facts in the case is to be doubted, yet it may be well to call attention to the fact that the giant cell is considered a pathological index of a mild or healing process as contrasted to a leucocytic or monocytic reaction which spells either a progressive or highly active process. The futility of placing too much reliance upon histological findings alone for diagnostic purposes is evident from our present knowledge of the cellular responses to tuberculosis as well as a recognition of the difficulty of examining more than a small portion of tissue by histological and microscopical methods.

The data tabulated in Table III appears to bear out the observations made on tuberculous individuals recorded in Tables I and II in that the histological tissue changes are unreliable as evidence for the presence of tuberculosis in anorectal fistulae. In 2 of 106 cases the findings were negative by bacteriological methods (with guinea pig and culture test) which revealed in sections typical giant cells, while in 15 of these 106 specimens evidence was presented of a cellular reaction (monocytic, histiocytic, and epithelioid cells) such as occurs in tuberculous conditions but which should not be considered specific for this condition alone. The striking result, however, to be noted from a careful examination of all this data is that tuberculosis of ischio-rectal abscesses and anorectal fistulae is practically limited to individuals with pulmonary tuberculosis evident by clinical and roentgenological examination. The incidence

appears to be slightly less in the favorable inactive or arrested types of pulmonary tuberculosis. It would appear also that the factors which are at play in permitting the invasion of the ordinary pyogenic organisms into the anorectal region and thus favor the production of abscesses or fistulae in this region also permit the entrance of the tubercle bacillus into these regions the original sources probably being the pulmonary focus with heavily laden bacillary discharge which on its course to being discharged from the body passes over certain predilection sites and favored by mechanical conditions, results in laryngeal, ileocecal and rectal localizations the sites of stasis and frequent mechanical tissue injury permitting entrance and then a suitable place for abscess formation with its ultimate rupture and fistula. Although the anorectal condition is dependent more or less upon the outcome of the pulmonary condition rectal hygiene can do much to prevent this condition and proper therapy based on the co-operation of the proctologist and the internist can do a great deal to remove it and prevent recurrences.

SUMMARY AND CONCLUSIONS

As a result of a review of the literature and a bacteriological and histological study of

tissue from ischio-rectal abscesses and ano-rectal fistulae in a series of 155 cases in which 106 patients were free from evidences of pulmonary tuberculosis, 18 had an inactive arrested fibroid phthisis and 31 had an active pulmonary tuberculosis, the following summarized conclusions are presented.

Tubercle bacilli are found by bacteriological methods (guinea pig inoculation and culture tests) in patients with ischio-rectal abscesses or ano-rectal fistulae only if pulmonary tuberculosis is present. Tubercle bacilli were found in 77 per cent of our patients with active and in 55 per cent with inactive (arrested or fibroid) pulmonary tuberculosis but they were not isolated in the 106 cases in which the patients were free from evidences of pulmonary tuberculosis. These findings suggest a close etiological relationship between tuberculous ischio-rectal abscess or ano-rectal fistulae and pulmonary tuberculosis. Histological methods were found unreliable for determining the tuberculous nature of ano-rectal conditions except possibly in the presence of marked involvement with typical tubercle formation and the presence of acid fast bacilli which was not a common finding in this series. The presence of giant cells or granulomatous tissue with monocytes and epithelioid cells proved not definitely pathognomonic of tuberculosis in the ano-rectal region. Acid fast bacilli are not commonly found in sections or smears from tuberculous ischio-rectal abscesses or ano-rectal fistulae with the aid of the microscope even though they

are readily found by reliable culture methods or guinea pig inoculation.

The author is most grateful to Dr. H. J. Corper, and to Drs. Maurice L. Cohn and Nao Uyeki for their untiring cooperation in completing the bacteriological investigation.

EXCRETION OF BILE PIGMENTS IN EXPERIMENTAL OBSTRUCTIVE JAUNDICE¹

UDALL J. SALMON, B.Sc., M.D., C.M., CHICAGO

THE question as to whether bile pigments are excreted into the intestinal tract in obstructive jaundice has received but little attention from investigators. Only two references to the subject were found in the literature. Wilbur and Addis while investigating the origin of urobilin, detected traces of this substance in the stools of dogs with common duct occlusion as well as in animals with complete biliary fistula. These workers concluded that urobilin was excreted into the gastro-intestinal tract as such from the blood stream. Wallace and Diamond, in the course of their liver function studies, found small quantities of urobilinogen in the stools of dogs with common duct occlusion and concluded that the urobilinogen originated from bilirubin eliminated into the gastro-intestinal tract from bilirubin saturated plasma.

Our attention was drawn to the subject by the finding of bile pigments in the aspirated stomach contents of a patient with longstanding obstructive jaundice. This was interpreted as indicating that the obstruction was not complete and that some communication had been established between the biliary system and the bowel. The question, however, was raised whether the obstruction might not, nevertheless, be complete and the bile staining of the stomach contents be explained on the basis of elimination into the bowel of bile pigments with the gastro-intestinal secretions.

Both Wilbur and Addis and Wallace and Diamond arrived at their conclusions concerning the excretion of bile pigments into the intestinal tract from a study of the stools alone. Apparently neither of these groups of investigators looked higher up in the intestinal tract for bile pigments. It seems logical to suppose that if in obstructive jaundice, bilirubin is eliminated into the intestinal tract, it should be possible by examining specimens of stomach and small bowel contents to detect this pigment before it has been transformed into urobilinogen and urobilin. The following ex-

perimental study was undertaken with this in view, namely to produce obstructive jaundice in animals and then (1) to study the bile pigment content at various levels in the gastro-intestinal tract and (2) to study the relationship of the elimination of these pigments (a) in the bowel and (b) in the urine, to the level of blood bilirubin concentration.

EXPERIMENTAL PROCEDURE

Dogs were used for all experiments. The animals were kept in metabolism cages and fed on a mixed diet. Operations were performed with aseptic technique, under ether anesthesia. After a preliminary period of 1 or 2 days during which the blood, urine and stools were examined for bile pigments, the common duct was ligated and resected about 1 inch from the duodenum in 16 animals. In 6 others a cholecystectomy was performed in addition to the common duct ligation. The stools were thereafter examined each day for bilirubin, urobilinogen, and hydrobilirubin. Blood bilirubin and urine bilirubin determinations were made daily.

During the earlier part of this work, 4 of the animals were explored after they had developed a pronounced generalized icterus. The biliary ducts were inspected to verify the absence of any communications with the bowel. Specimens of the contents of the bowel were removed through small incisions in the stomach, small bowel, and proximal colon and examined for bilirubin and urobilinogen. This practice was, however, discontinued because 3 of the animals expired during the operation and 1 several hours afterward. Since the operation occasioned little surgical trauma and very little loss of blood, we attributed the cause of death to the anesthetic. Ether had been used for 2 animals and nembutal, in minimal doses for surgical anesthesia (25 milligrams per kilogram body weight, given intravenously), proved equally fatal in the 2 others. The remaining

animals were explored only after death when specimens were taken from the stomach small bowel and colon. At necropsy each animal was examined to verify the completeness of the occlusion of the common duct and to ascertain the absence of anomalous communications between the biliary channels and the bowel. The method of obtaining specimens from the bowel was as follows: The bowel was incised and gross particles of food if present, were discarded. The material in the bowel was removed with a dull porcelain spoon care being taken not to scrape the mucosa. In some animals the bowel contained so little material that rather than risk scraping the mucosa, a segment of the bowel was rolled longitudinally and the contents gently expressed.

The chemical methods employed were

I. *Feces* (1) Schmidt's test for hydrobilirubin. (2) Huppert's test for bilirubin. (3) Urobilinogen was determined according to the method described by Wallace and Diamond.

II. *Gastro-intestinal contents* in addition to those enumerated above the following test for bilirubin was also used.

To about 10 grams of the fresh material to be examined 25 cubic centimeters of 0.1 per cent potassium hydrosulfide is added and the mixture vigorously shaken for several minutes, and centrifuged. To 2 cubic centimeters of the supernatant fluid, 2 cubic centimeters of the hydrochloric acid-sodium nitrate¹ reagent described below is added. In the presence of bilirubin the solution will turn green. This test is an adaptation of the quantitative urine bilirubin method described by Sabatini. We found this test much more sensitive than any of the other qualitative tests. Unlike the van den Bergh this test is specific for bilirubin since the development of the green color depends upon the oxidation of bilirubin to biliverdin.

III. *Blood* Blood bilirubin was determined by the quantitative van den Bergh method. The standards described by van den Bergh are not of exactly the same shades as those

produced in the serum. Nichols and Jackson have described standards with more comparable colors. Comparison is made grossly against a series of standards in a comparator box. We have found this method adequate for the determination of variations of blood bilirubin concentration that exceed 1 milligram per 100 cubic centimeters. For the determination of changes of less than 1 milligram we have employed the microcolorimeter with the same standards of Nichols and Jackson.

Experimental results Excretion of bile pigments into the gastro-intestinal tract.

Feces Tests for bilirubin were always negative in the stools of all animals. Tests for hydrobilirubin became totally negative in all cases after the second to the fourth day after operation, and remained so until death. Frequently no trace of hydrobilirubin could be detected during the preliminary period in normal dogs. We gained the impression that Schmidt's test for hydrobilirubin is of very little use in the detection of bile pigments in the stool though it is widely used by clinicians for this purpose.

The stools were always positive for urobilinogen in the preliminary period but in most experiments this substance began to disappear about 3 to 6 days after occlusion of the common duct. After the seventh post-operative day the stools remained constantly negative for urobilinogen until death in 16 of the 22 animals. Traces of urobilinogen were found constantly in the feces of 3 (Nos. 13, 19, and 21) of the 6 remaining. In the 3 others (Nos. 7, 10 and 23) urobilinogen disappeared from the feces for periods of 26, 23 and 24 days, respectively. The urobilinogen thereafter reappeared in these cases in the stools and persisted until death. The blood bilirubin in these at the time when urobilinogen began to appear in the stools was 54, 30 and 28 milligrams per 100 cubic centimeters, respectively.

Of the group that was constantly positive for urobilinogen, at autopsy one (No. 19) had a gastric ulcer another (No. 13) had diffuse ecchymotic areas in the mucosa of the large bowel, and the third (No. 21) exhibited nothing unusual apart from the marked generalized icterus and markedly engorged bile

¹Reagent. Concentrated hydrochloric acid, 25 cc. Water to 100 cc.

²Reagent. 1% sodium nitrate.

³T. 30 cc. of solution 1, 5-6 cc. of solution 2. This reagent must be prepared only as required, since it deteriorates after several hours.

passages. The constant presence of urobilinogen in the stools of Nos. 19 and 13 is probably attributable to hæmorrhage into the bowel. With hæmorrhage bilirubin is introduced into the bowel which would account for the urobilinogen in the stools. No. 21 remains a puzzle. The possibility of bile entering the intestinal tract through some aberrant bile duct as well as the existence of some lesions in the gastro-intestinal tract which might ac-

count for hæmorrhage into the bowel were excluded at autopsy.

GASTRO-INTESTINAL SECRETIONS

The specimens removed from the group of 4 jaundiced animals that were explored under ether and nembutal anaesthesia were all negative for bilirubin and urobilinogen. The results of the remaining 18 that were examined after death are summarized in Table I.

Traces of bilirubin were found in the stomach of only 1 animal (dog 7) in the small bowel of 7 animals, and in the colon of none. Of the 7 that had traces of bilirubin in the small bowel the stools of 6 were positive for urobilinogen before death. Urobilinogen was found in the colon of all cases in the small bowel of which bilirubin had been found.

No urobilinogen was ever detected in the stomach and only once in the small bowel (No 7). Dog 7 presented two unusual features—presence of bilirubin in the stomach and of urobilinogen in the small bowel. This animal presented other interesting features that merit recording. The animal lived for 72 days with a complete obstruction of the common duct. At necropsy the peritoneal cavity contained 110 cubic centimeters of clear amber colored ascitic fluid. This fluid contained 40 milligrams of bilirubin per 100 cubic centimeters but no urobilinogen. The gall bladder was distended to about five times its normal size. The liver was cirrhotic.

DEDUCTIONS FROM EXPERIMENTS

On studying the experimental results summarized in Table I certain facts are noted:

1. If an animal survives long enough after a common duct occlusion bile pigments will appear in the gastro-intestinal tract. Bile pigments were found in the intestinal contents of all animals that lived more than 30 days after the experimental obstruction and none was found in the intestines of animals who survived for a shorter period.

2. Urobilinogen can be detected in the stools of animals with complete obstruction of the biliary ducts if the obstruction is of long duration. After death bilirubin was found in the small bowel of all these animals the stools of which had been positive for urobilinogen. In 1 animal (No 22) with stools negative for urobilinogen traces of bilirubin were found in the small bowel and of urobilinogen in the colon. Since it is a well established fact that urobilinogen is absorbed from the intestines, the absence of urobilinogen from the feces in this case is probably accounted for in this manner.

3. The blood bilirubin concentration must attain a certain level before bile pigments will

be excreted into the bowel. The blood bilirubin concentration exceeded 22 milligrams per 100 cubic centimeters in all animals that had bile pigments in their intestines. It seems however that the blood bilirubin concentration is not by itself the determining factor in the elimination of bilirubin into the bowel since in one animal (No 30) the blood bilirubin rose to 28 milligrams before death and no bilirubin or urobilinogen was found in its gastro-intestinal tract whereas, three other animals were eliminating bile pigments into the intestinal tract at lower blood bilirubin levels (No 13 at 26 milligrams, No 21 at 26 milligrams, No 22 at 24 milligrams). The degree of saturation of the tissues with bile pigments is probably the deciding factor in the elimination of these pigments into the intestinal tract.

4. Certain pigments are found only in certain portions of the bowel which are anatomically and physiologically distinct from each other. With but one exception to the entire series, bilirubin was found only in the small bowel and urobilinogen only in the colon.

The absence of bilirubin from the colon and urobilinogen from the small bowel is in agreement with the commonly accepted theory of urobilinogen formation. The bilirubin in the bowel is believed to be reduced by bacterial action to urobilinogen. While this process may take place to some extent in the lower part of the small bowel in only 1 case (No 7) was urobilinogen detected here.

URINE BILIRUBIN EXCRETION

The second part of this experimental work concerns itself with a quantitative study of the relationship of blood bilirubin concentration to bilirubin excretion in the urine. Since Mann and his co-workers (1) have shown that the bilirubin content of arterial blood is the same throughout the body while the bilirubin content of the blood of the accessible veins varies, all blood specimens were obtained from the femoral artery except where otherwise indicated.

Method. The colorimetric method of Saha and his co-workers (2) was used to determine the bilirubin concentration in the urine. The method consists

in the oxidation of bilirubin by a hydrochloric acid sodium nitrite mixture to biliverdin with the formation of a green color. This color is then compared in a colorimeter with an artificial standard (a mixture of chrome alum and potassium dichromate) representing a concentration of bilirubin of 1 to 1000. Although the author fails to mention it, the colorimetric standard can only be used with daylight since artificial light brings out a reddish phosphorescence in the standard. Specimens of urine should be examined

Fig. 5. Relationship of blood bilirubin concentration to urine bilirubin concentration and output in milligrams per hour following experimental obstructive jaundice.

while fresh, since a certain amount of bilirubin disappears from the urine on standing at room temperature. Specimens can however be kept in the refrigerator for 12 hours without the loss of appreciable amounts of bilirubin. Urines which have undergone ammoniacal decomposition yield colors which cannot be compared with the standard. Particular care should be taken to keep the urine clear of faeces. Particles of faeces soaking in the urine will interfere with the development of the characteristic green color.

In the experiments the specimens were collected immediately or shortly after voiding and filtered. The bilirubin determination on the specimen was then performed immediately. If the animal voided in the evening a few drops of toluene were added and the specimen placed in the refrigerator and examined in the morning. At the end of each 24 hour period the animals were catheterized.

The color of the urine after the addition of the reagent at times did not exactly match the shade of the standard. This was more noticeable in urines of low bilirubin concentration (3 to 5 milligrams per 100 cubic centimeters). Urines containing concentrations of bilirubin

above 10 milligrams per 100 cubic centimeters always yielded shades comparable to if not identical with the standard. While the method will not enable one to measure quantitatively the traces that occur in the urine below concentrations of 3 or 4 milligrams bilirubin per 100 cubic centimeters of urine, it is adequate for the quantitative measurement of the variations in bilirubin concentrations that occur in the urine following common duct occlusion.

Experimental results. The results of a typical experiment following common duct occlusion are given in Table II (Fig. 1). The gradual rise in blood bilirubin is paralleled by corresponding increases in the bilirubin excretion. Table III shows the more rapid rise of bilirubin in both blood and urine which occurs when a cholecystectomy is performed in addition to occlusion of the common duct. If the gall bladder is allowed to remain it seems to act as a reservoir for bile leading to a slow gradual rise in the blood bilirubin. In 2 of the 6 animals upon which cholecystectomies were performed, there occurred a rapid rise in blood bilirubin (Table III) followed by a falling of the blood values for several days, and in turn

by a steady rise until death. Urine bilirubin values paralleled the blood bilirubin fluctuations. The maximum value for blood bilirubin observed was 54 milligrams in dog 7 and occurred 72 days after common duct occlusion. The corresponding urine bilirubin concentration in the same animal was 270 milligrams per 100 cubic centimeters. This is a ratio of blood bilirubin to urine bilirubin concentration of 1.4. The highest ratio (1.8) occurred in dog 6. Blood bilirubin was 5 milligrams and the corresponding urine bilirubin 40 milligrams per 100 cubic centimeters. The curves of blood and urine bilirubin concentration did not always run parallel. The rate however of bilirubin excretion always paralleled closely the variations in the blood bilirubin concentration (Fig. 1).

In Table IV are given the results of an experiment in which arterial and venous blood and urine specimens were collected at half

hourly intervals. In order to ensure the simultaneous collection of arterial and venous specimens the femoral artery and vein were exposed. Mann and his co-workers (1, 2) using a spectrophotometric method for the determination of bilirubin reported higher blood bilirubin concentration in the femoral vein than in the blood drawn simultaneously from the femoral artery. We were never able to demonstrate differences of greater magnitude than 0.5 milligram between arterial and venous samples and these, not constantly. It is significant, however, that when differences were detected, the venous blood values were always higher than the arterial.

In 3 animals several days before death a drop in the blood bilirubin values and a corresponding fall in the bilirubin excretion occurred, which continued until death (Table V). Postmortem examination of these animals revealed nothing to explain the terminal drop in blood and urine bilirubin. The common duct occlusion was complete in each case and no anomalous communications between the bile passages and the bowel were found.

CONCLUSIONS

1. In complete obstructive jaundice of long duration in dogs, bile pigments are eliminated into the gastro-intestinal tract and can be detected as bilirubin in the small bowel and urobilinogen in the large bowel. Urobilinogen can be found in the stools of the same animals although Schmidt's hydrobilirubin test which is widely used clinically for the detection of bile pigments in faeces was constantly negative.

2. The elimination of bile pigments into the bowel seems to be determined by a combination of factors. (A) The blood bilirubin concentration (23 milligrams per 100 cubic centimeters of blood was the lowest blood bilirubin level at which bile pigments were found in the intestinal tract). (B) The duration of the complete biliary obstruction. (Bile pigments were never detected in the intestinal tract of animals who lived for less than 30 days after the common duct occlusion.)

PYELOMETRY

A GRAPHIC STUDY OF THE CONTRACTIONS OF THE KIDNEY PELVIS¹

J. LEON JONA, D.Sc. (ADELAIDE) M.D. (MELBOURNE) M.S. (ADELAIDE) F.R.A.C.S. MELBOURNE, AUSTRALIA
Senior Assistant Surgeon, Women's Hospital, Melbourne

In former communications the author has drawn attention to the study of the normal and pathological physiology and pharmacology of the kidney pelvis by means of pyeloscopy and of pyelometry in both the human being and in the experimental animal. In the present communication some results of the pyelometrical study of the kidney pelvis in the human being are submitted. The scope of the inquiry is, of course, limited by the material and facilities available in all cases the observations recorded by pyeloscopy, pyelography and pyelometry were studied in association with the clinical findings. Obviously in the human being the study of the action of drugs was limited by the pharmacological requirements of the case and the therapeutic indications as suggested by animal experiments (3).

With the conscious assistance of the patient the effects of various procedures could be investigated such as sitting up, lying down, lying on the affected side, lying on the opposite side, coughing, deep respirations, Valsalva's experiment (forcible expiratory effort with closed glottis at the end of inspiration) and alterations of posture by altering the inclination of the table on which the patient lay.

METHOD

A ureteric catheter as large as possible up to 7 or 8 Charnière was passed into the pelvis of the kidney. The position of the eye of the catheter was verified by examination under the fluorescent screen and the filling of the kidney pelvis with abrodil or uroselectan B solution was carried out under direct vision through the screen. The kidney pelvis being filled its contractions were observed and the passage of the globule down the ureter alongside the indwelling catheter observed. (This was obviously not a normal state of affairs but the findings could be verified by subsequent pyeloscopy after removal of the catheter.)

It is recognized that the presence of an abnormal fluid in the kidney pelvis is not a normal state of affairs and that the injection of this fluid into the pelvis through the indwelling ureteric catheter also introduces an unknown factor but, until pyeloscopy is possible with the dye in the pelvis excreted there by the kidney after oral administration or parenteral injection such as is done in intravenous pyelography the method must stand.

The kidney pelvis was then emptied of abrodil and washed out with normal saline and then connected up as illustrated in a previous paper (2 Fig. 1).

Drugs investigated were injected subcutaneously or intramuscularly. It is recognized that the intravenous route would be experimentally more desirable but this is not always clinically expedient. Again the drugs were used only in therapeutic doses and so the human being of 50 kilograms would receive intramuscularly or subcutaneously the same dose of such drugs as pituitrin, eserine, strychnine, atropine as the dog of 8 to 10 kilograms received intravenously and in the case of histamine and morphine a smaller dose. This may account for some of the differences noted.

RESULTS OBTAINED

In all tracings upward movement indicates contraction and downward movement relaxation. Time 90 mm = 1 minute. The normal tracing. The apparently normal tracing (Fig. 1) shows a series of small waves, generally 2, 3 or 4 in number superimposed on larger waves—generally on the ascending limb of the wave, but sometimes on the descending limb. I take these small waves to indicate contractions of the calyces while the large wave indicates contraction of the pelvis itself ("ventricle"). The rhythm is regular and the height of the contractions more or less constant.

1. *Effects of posture in the normal.* (a) Sitting up causes a marked and rapid rise in

pressure up to a maximum when the tracing maintains a plateau. It sometimes however, gradually falls after reaching maximum level. In the latter case I take it that the urine under pressure in the pelvis is escaping *alongside* the catheter and so the pressure falls (Fig 2)

b On lying down after a momentary slight rise in pressure due perhaps to muscular effort the pressure falls rapidly to normal (Fig 2). The same effects were produced by raising the head of the table and then restoring the patient to the horizontal without any apparent conscious effort on the part of the patient

2 *Increased intra-abdominal pressure* induced by muscular movement coughing laughing Valsalva's experiment all produce a rise in pressure in the kidney pelvis which is what one would expect (Fig 3). If the patient is made to sit up first and then told to strain cough or Valsalva there is a further rise superimposed on the first rise and this second is often as great as that induced by the same procedure with the patient lying down. With a small inlying catheter, if these procedures are repeated several times in quick succession the response becomes less. I think this is due to the emptying of the pelvis down the ureter alongside the catheter

3 *Effect of drugs in the normal* Histamine in the doses given (grain 1/22 to grain 1/44) injected intramuscularly induces contraction of the kidney pelvis (Fig 4)

Atropine apparently causes contraction in the experimental animal (dog) (2) although in the human being relaxation is generally seen but sometimes a contraction is obtained (Fig

All tracings are comparable the time relations being the same and are all drawn to the same scale (1 to 1) from the original tracings.

Fig 1 Normal tracing I Mrs. B. Note calycinal contractions on upstroke i.e. during systole of the pelvic "ventricle." II Mrs. D. Note calycinal contractions on the downstroke i.e. during diastole of the pelvic ventricle. The difference in rate of ventricular contraction may have a bearing on this.

5) Apparently this effect is due to cutting out of vagal action (3)

Pituitrin generally produces a rise with 'flattening' of the wave and obliteration of the rhythmic contractions.

Eserine causes contraction although this is generally better seen pyeloscopically than graphically. It was also noticed that after eserine a much greater contraction was obtained when the patient sat up than was obtained before eserine was injected (Fig 6)

In pathological cases (a) In mild degrees of hydronephrosis (capacity of pelvis 15 to 20 cubic centimeters) the tracing obtained showed very shallow waves

1 *Effects of sitting up* The rise induced by sitting up was very much less than in the normal. When however this procedure was repeated several times, a higher and higher response was obtained *with relief* of pain and the contractions of the calyx were better and larger. This confirms what one finds on pyeloscopy. This type of pelvis will be seen to contract well when nearly emptied and with

Fig 2 Effects of sitting up and lying down (see text) I Mrs. McL. same patient as in Figure 9 but normal (opposite) side. II Mrs. D. same patient as in Figure 1 tracing II

Fig. 5. Effects of sitting up, lying down, raising intra-abdominal pressure by Valsalva's experiment. I Mrs. I (normal) case. Small catheter. Cervical contractions not shown. II Mrs. W., slight dilatation of pelvis (capacity 5 cubic centimeters).

only 1 or 3 cubic centimeters abridgment solution run in. When however 15 or 20 cubic centimeters are run in the contractions are poor and the patient may complain of discomfort. Apparently the effect of sitting up and lying down several times in quick succession is practically to empty the overfilled pelvis with relief of pain.

2 *Effects of drugs.* Pituitrin appears to increase the tone in these cases without much increase in intrapelvic pressure as a result of the drug (Fig. 7). This is seen in the more marked response to sitting up than was seen before whereas in other cases a smaller response is obtained owing to the pelvis already being in a state of contraction.

In cases of dysfunction—irregular contractions associated with pain (Fig. 8) 1 *Effect of posture.* In some cases after the rise induced by sitting up the contractions become regular and pain is relieved (Fig. 8).

2 *Effects of drugs.* Pituitrin in these cases often does not produce so much a rise in intra-pelvic pressure as a steadying of the pelvic contractions with production of regular waves (Fig. 8). In all cases of irregular contractions

with pain wherever the irregularities were corrected by posture or drugs the pain was relieved. With the return of the arrhythmia, the patient complained of pain once more.

RESULTS

The results so far obtained encourage one in the hope that the graphic method may give us information which can be studied at leisure and collated with pyelographic, pyeloscopic and clinical findings. The effects of posture are at first rather startling and will explain the beneficial results obtained by posture in some cases of pyelitis and in some cases of kidney pain. The apparent benefit derived from massage of the kidney region in some cases can also be understood when it is borne in mind that this massage may induce a rise in the intrapelvic pressure which would facilitate emptying of the pelvis and assist in overcoming slight spasm in ureter or pelvi-ureteral junction.

In regard to the action of drugs, as a rule the results obtained in the experimental animal (2) were confirmed but in some cases one obtained an apparent reversed action, but

Fig. 4. Action of histamine injected intramuscularly. Mrs. B. Compare Figure 1 tracing 1.

whether this was due to the well known phenomenon of the reversed action of smaller dose or to the inherent difference in reaction of the human being and the dog to these particular drugs has not so far been fully investigated but such experimental observations as were made suggested the former

This was particularly the case with atropine and with histamine. Atropine in the doses given gave an apparent contraction of the pelvis in some cases but this contraction may have been secondary and due to cutting out of vagal action. In other cases relaxation of the pelvis with overfilling and consequent pain was obtained.

With regard to histamine a very definite rise in pressure was obtained in most cases with the doses given.

In neurotic women and women who were the subjects of spasm in the ureter or dysfunction of some kind as observed by pyeloscopy, it was seen that the normal contractions of the pelvis and calyces were much shallower than normal and sometimes hardly apparent. In these cases pituitrin, eserine and strychnine often failed to produce any further contraction so that the pelvis was apparently in a condition of hypertonic contraction. In these cases quinine grains, 5 given 3 times a day, generally caused relaxation (3) and relief of pain. The pyelo-ureterogram of such a patient is illustrated (Fig 9). After a course of quinine she is now apparently quite well and free from pain.

In other cases (Fig 8) also the tracing showed an irregular series of waves accompanied by pain and when the waves became regular the pain disappeared.

In studying these tracings one wonders whether the information obtained by the graphic method in other fields of investigation

Fig 5 Action of atropine

can assist us. The differences in amplitude of the waves obtained with the same size catheter and equal conditions in the recording apparatus in different patients suggest the possibility of these waves being some index of calyceal or pelvic output.

As S W Patterson and F H Starling (5) point out in regard to the heart the output is equal to and determined by the inflow and as long as arterial resistance is not raised the cardiac output may reach enormous proportions. If however the resistance to output is raised the venous pressure rises and the output may be appreciably affected. If the same set of conditions hold in regard to the kidney pelvis as in the heart, then we may establish the parallel in this wise. The outflow through the ureter corresponds to the outflow through the great arteries, the body of the pelvis corresponds to the ventricle, the calyces to the auricles and the urine flowing in to the calyces from the collecting tubes corresponds to the venous inflow via the great veins. Now if the parallel still holds then the output is equal to and is determined by the inflow and as long as there is no resistance to output the pelvis can cope (within wide limits) with whatever amounts of urine are poured in. If however the resistance to the output is raised then the pressure in the 'ventricle' and calyces must rise till it reaches the secretion pressure of the urine when the flow must cease. We thus see what far reaching effects may be produced on the kidney locally and

Fig 6 Action of eserine. Effects of sitting up and lying down before and after injection. I Before eserine. II After eserine.

Fig. 7. Action of pituitrin. Note improvement in calyceal contractions in III after injecting pituitrin. II Improved response to sitting up after pit. trtn.

Fig. 8. Pelvic muscle dysfunction. Irregular contractions associated with pain. Pain relieved when contractions regular. In tracings 1 and 2 pain was associated with irregular contractions. Pain was relieved when contractions became regularized. 1 by injection of pituitrin (Mrs. B. Fig. 1). 2 by injection of pituitrin after sitting up and lying down several times (Mrs. D. Fig. 1).

the system generally by conditions of spasm or physical obstruction or kinking in the ureter. Recognizing how frequently one sees spasm of the ureter with or without antiperistalsis in the neurotic (especially when some condition in the urine such as crystals of phosphate, oxalates or uric acid act as exciting causes of ureteric spasm) one wonders how often the vague backaches and headaches in these people may really be attributable to some actual disorganization of kidney function on the lines outlined above.

We do know that in many of these patients the outflow of urine from the ureter to the bladder is not regularly and evenly distributed over a unit of time. The complete interpretation of the tracings obtained must how-

ever be deferred until a larger series has been obtained.

There is another point suggested by these tracings which is borne out by pyeloscopy. In observing a pelvis comfortably filled with a watery solution of abrodil 10 or even 20 contractions of the pelvis are often required to empty the pelvis. This suggests that the pelvis does not completely empty at each systole but retains a maintenance filling of urine and as this is added to by the systole of the calyces, the contraction wave in the ventricle forces this excess out. The height of the waves, therefore, may be an indication not of the "pulse pressure" in the pelvis but of the actual amount of fluid displaced from the pelvis at each systole.

We do know that in many cases of hydro-nephrosis the pelvis may hold quite an amount of urine which runs away in a steady stream when the ureteric catheter is passed into the pelvis whereas in some cases of spasm of the pelvis practically no urine drips from the catheter on passage the outflow being intermittent from the outset. If the maintenance filling varies in amount according to varying physiological conditions of circulation posture rate of secretion alterations in tone of the pelvis spasm or obstruction of the ureter by pressure from adjacent structures then it is easy to see how this variation may be reflected in alterations in amount or rate of kidney secretion while at the same time a variation in the direction of over filling or complete emptying may determine some of those obscure kidney pains which are so difficult to define and elucidate and which yet often reduce the patient to a condition of semi invalidism. A great deal more work is required on these lines before authoritative statements can be made on the subject but the results so far obtained by pyelometrical investigation of patients give one permanent records which can be compared with subsequent tracings and studied in connection with past or subsequent clinical findings. This preliminary investigation is also submitted in the hope that it may stimulate others with better facilities than the author possesses to carry out more extensive investigations on similar lines.

Fig. 4. Case 1. Postmortem roentgenogram. Still greater displacement of neighboring structures. Note complete absence of lung markings on spine. There is marked decrease in density of the upper lobe, probably due to compensatory emphysema.

LARGE PULMONARY AIR CYSTS OF INFANCY

WITH SPECIAL REFERENCE TO PATHOGENESIS AND DIAGNOSIS¹

WILLIAM E. ANSPACH M.D., AND IRVING J. WOLMAN M.D. CHICAGO

APPROXIMATELY 150 cases of congenital lung cyst have been recorded in the American and European literature but only a few of these were in infants and in fewer still was the condition diagnosed and its course watched during life. In most instances the lesion was an accidental finding at necropsy.

In the 2 cases that we are about to report the diagnosis was made early and the patients were observed for a considerable time before death. The clinical and roentgen observations taken together with the necropsy findings suggest to us an explanation of the nature of air-containing lung cysts. This explanation is somewhat different from any of the many theories heretofore advanced as the result of necropsy study alone.

CASE 1. Balloon cyst. M. B., a white male premature infant had had a normal birth but was kept in an incubator for 10 days because of his small weight of 3 pounds 6 ounces. He was breast fed and seemed to develop normally until 7 weeks of age when his respirations gradually became difficult and rapid and a slight cough appeared. Physical examination by an attending pediatrician revealed a subnormal temperature and chest findings which were attributed to an atelectatic lung. There was no cyanosis or fever. The symptoms grew steadily worse and he was admitted to the Children's Memorial Hospital on September 3, 1931, 2 weeks after the onset of symptoms. At this time, 9 weeks of age, he weighed 6½ pounds. There was dullness and absence of breath sounds on the right side of the chest, and the point of maximum cardiac impulse was found slightly to the left of the mid sternum. Many rales were heard in the left lung. There were no evidences of congenital syphilis. The red count was 5,300,000, the hemoglobin 55 per cent and the white count 15,400 with a normal differential count. The diagnosis based on the physical findings was congenital atelectasis of the right lung in a premature infant. An X-ray examination on the following day (Fig. 1) showed a dense shadow obliterating completely the lower half of the right lung field. Above this lay a dome-shaped pocket of free air which had as its lower border a horizontal fluid level. Above this air pocket lay normal air containing lung tissue. These findings were interpreted as a right hydropneumothorax.

The infant took feedings well. There were frequent attacks of difficult breathing with cough and slight cyanosis. Between paroxysms he was not cyanotic but breathed rapidly. *He coughed up some viscous mucoid fluid on one occasion.* Another X-ray examination (Fig. 2) made 4 days later showed complete disappearance of the density from the right lung field. In its place was a large air-containing cavity. A thoracentesis had not been done. In successive roentgenograms this cavity gradually increased in size, pressing the mediastinal structures to the left and also the right leaf of the diaphragm downward. There was no evidence of a collapsed lung at the right of the spine. The apex of the right lung grew smaller and less dense as the amount of air increased in the cavity below. The diagnosis of pneumothorax was made although one attending physician (Dr. E. T. McNary) suggested the possibility of a lung cyst.

Labored respirations with cyanosis continued and when 10 weeks old a thoracentesis needle was

Fig. 5. Case 1. Anterior and diaphragmatic views of specimen (after fixation).

Fig. 6. Case 1. X-ray picture of specimen after cyst was filled with barium and gelatin.

inserted to reduce the pressure. About 150 cubic centimeters of air was withdrawn followed by relief of symptoms for but a few minutes. An X-ray (Fig. 3) taken 30 minutes later did not show the expected diminution, but instead an enlargement of the air containing space. Respiratory difficulty and cyanosis continued until death occurred 1 week later (age 11 weeks). Fever was not present at any time. Postmortem films (Fig. 4) showed the cavity to be larger and the mediastinal displacement even greater than in the films taken during life.

At necropsy the body was small, poorly nourished, but well developed. It measured 45 centimeters in length and weighed 5 $\frac{1}{2}$ pounds. The thorax was well formed and symmetrical. No

Fig. 7. Case 1. Injection of tracheobronchial trees showing broochial distribution to region of cyst.

abnormalities were found except those within the chest. When an incision was made through the right costal cartilages, the sound of escaping air was heard.

A cyst like air containing chamber was found within the middle lobe of the right lung. It occupied practically the whole right side of the thorax and displaced the mediastinal structures to the left. The left lung was compressed and pushed behind the heart. The heart was normal. Laterally the cyst wall was loosely bound to the right costal pleura. It could be freed by blunt dissection, although the thin and delicate wall ruptured in a few places during this process. The other lobes were free from cysts, had a normal architecture, and were apparently not

of the lung where they were well marked. The lower lobe lay posteriorly extending to the left of the spine. The small upper lobe sat on the cyst like a

Fig. 13. Large cyst-like pneumothorax following pneumonia and empyema. Although there are changes in the upper lobe and hilum shadows, knowledge of the clinical course is necessary to differentiate it from a large solitary cyst.

cocked hat. Atelectatic middle lobe parenchyma was present on the posterior aspect of the cyst, and also on the medial surface adjacent to the mediastinum.

Fig. 15. Massive positive pressure pneumothorax following empyema. Arrow shows collapsed lobes which have retracted from the diaphragm. This point aids in the differentiation from lung cyst.

Fig. 14. Bullous emphysema secondary to congenital atelectasis. Appearance easily confused with multiple air cysts. A comparison with other films of this case ruled out cysts because of the lack of uniform arrangement of film densities at different examinations.

num. The cyst formed the lateral and anterior aspects of the middle lobe and its inferior surface rested on the diaphragm. Its wall was thin and was supported by contiguous parenchyma and the parietal pleura. The lining was smooth and white,

Fig. 16. Eventration or herniation of the diaphragm, resembling multiple lung cysts, may be diagnosed by the appearance of opaque shadows in this portion of the lung field following a barium meal.

and a fine deposit of white granular matter clung to the lower portion. At the hilum there were a few dimples and puckerings and when the lungs were insufflated under water a stream of bubbles came from this region.

The right main bronchus divided into two branches. The inferior branch extended into the lower lobe, the superior divided into a large trunk which ran to the upper lobe, and a short trunk which supplied the middle lobe (Fig 3).

Microscopic examination. The alveoli of the middle lobe were partially collapsed, but otherwise normal. In two different regions, atelectasis was complete and here groups of microscopic cystic chambers ramified through the parenchyma among the alveoli. These cavities were of different sizes and outlines, some being circular others long tortuous and branching. Some chambers were dilated and filled with a clear albuminous coagulum their inner surfaces being outlined by flat cells of mesothelial character. The walls consisted of a thick layer of compact laminated fibrous tissue. Tiny fluid filled cysts, identical in structure, were situated in the wall of these larger ones (Fig 8a). A few chambers were collapsed, with inflammatory mononuclear cells and multinucleated giant cells within their lumen and walls. These small cystic chambers microscopic in size were situated in the neighborhood of the large air containing cyst (which had a similar structure). The wall of the latter was made up of laminated cellular fibrous tissue containing numerous scattered smooth muscle cells (Fig 8b). Occasional clumps of wandering inflammatory cells adhered to the inner surface. Its outer margin was somewhat indefinite and blended into the stroma of the surrounding atelectatic alveoli. In some sections, the wall of the cyst was thin consisting of only a single layer of connective tissue supported by collapsed alveoli nowhere however was the capsule completely absent. No elastic fibers could be stained within the walls of the cysts, or in any part of the lung tissue except the medial coat of the pulmonary arteries. No epithelial cells secretory glands, or prominent blood vessels could be found.

In the neighborhood of the middle lobe bronchus a small patent bronchiole (Fig 7) lined with columnar epithelium lay within the cyst wall. It seems highly probable that this was the channel of communication between the cyst cavity and the bronchial tree, although no direct communication was found in a series of sections.

The following anatomical diagnosis was made: prematurity congenital lymphangiectatic cystic formation in right middle lobe of lung communication between a large chamber and a terminal bronchiole with the formation of an air containing thin walled cyst displacement of heart and mediastinum to left, compression of left lung malnutrition.

PATHOGENESIS

Congenital pulmonary cysts are found in individuals of all ages and in a variety of

forms. They are usually multiple and may be scattered, grouped, or confluent. Usually they are restricted to one lobe occasionally the distribution is through both lungs. They may contain mucoid fluid desquamated matter air, or pus. A small percentage appear to be lymphangiomatous formations. Other cysts which arise from the mediastinum are derived from ectopic islets of the primitive gut and possess a lining of esophageal or gastric mucosa. The large majority of the cysts however possess a lining of cuboidal epithelium supported by fibrous tissue, smooth muscle, and cartilage, and seem to be bronchiogenic in character. For the pathogenesis of this last group a variety of theories has been proposed, including congenital bronchiectasis (11), excessive growth of interstitial fibrous tissue (13), defective energy of growth (18), underdevelopment of alveoli counterbalanced by widening of the bronchi (6, 24) and congenital atelectasis (10, 12). Congenital syphilis (28) fetal pleural adhesions (25) neoplastic processes (20), and bronchopneumonia (4) have also been suggested. All such speculations as to origin have been based almost entirely on the morphological evidence of necropsy findings. In most instances, postnatal changes caused by respiratory action rupture of the cyst or the presence of infection have confused and distorted the primary pathological picture. The reader is referred to a summary of 108 cases by Koontz (17) 1925 and to a more recent critical discussion of the theories of origin by Mueller (23), 1928.

There can be little doubt that the cysts found early in infancy are true congenital malformations arising from several different sources in embryonic life. However, once a large cystic cavity has been formed, its behavior should be determined largely by mechanical and accidental influences, such as capsular strength, proximity of adjacent air passages, plasticity of the surrounding lung tissue and the presence or absence of complicating respiratory infections, rather than by its embryogenesis or histology of its lining.

The consensus of investigators has been that large air cavities are preformed but col-

lapse at birth and distend at the first inspiration or else that they develop from small congenital bronchiectatic dilatations, which enlarge in postnatal life as the result of stenosis of their orifices. However a third possibility suggests itself the large air cyst may have been primarily a large fluid filled sac which evacuated itself spontaneously by rupture into a bronchus and became filled with air.

Just such an origin was manifested by our air containing cyst (Case 1) which originally had been a large fluid filled chamber within a congenital cystic malformation of the lung. While under observation its fluid content disappeared, presumably following rupture into a bronchiole. A small quantity of mucoid material was coughed up and the remainder was apparently swallowed. The emptying cavity instead of collapsing filled with air it then proceeded to dilate and balloon out as the result of valve like behavior of its bronchiolar opening and eventually produced respiratory difficulty and death. These changes were followed roentgenologically and verified at necropsy. So far as we have been able to determine this is the only instance where such a series of events has been followed clinically.

On histological examination the cystic formation appeared as a lymphangioma ramifying through the alveolar septa. Although the large majority of lung cysts reported have resembled epithelium lined bronchioles in Virchow's case and in those of Meyer and Kessler as restudied by Klebs, similar mesothelium-lined cysts, considered lymphangiectatic were scattered through the interstitial pulmonary framework.

Lung cysts are so rarely diagnosed during life that not much is known about their clinical behavior. When a large cyst is found in an adult one cannot say whether it had been present in essentially the same form since infancy or had recently developed or had changed its form and size within the past few years. The number of cases reported with satisfactory clinical studies is very small. The recent articles of Miller and Eloesser are doing much to arouse interest in the subject in this country.

We have found reports of 5 lung cysts which, at the time of discovery were large and air containing and which in their clinical behavior were identical with our case in its later stages. These occurred in infants in whom symptoms of respiratory distress had begun some weeks after birth. All showed extreme distention or steady increase in size. The cysts that were aspirated promptly re-filled with air. Those examined at necropsy were found to possess a narrow communication with some bronchiole which usually entered by a tortuous or oblique route. None of the patients survived 18 months of age. A brief review of each case follows.

An infant girl, having a large solitary air containing, expansile cyst was reported by Parmelee and Apfelbach. She had been seen at The Children's Memorial Hospital when 11 weeks of age because of frequent attacks of dyspnea and cyanosis, and presented clinically the signs of pneumothorax. Aspiration of air was followed by collapse necessitating the use of artificial respiration to maintain life. From that time on, the child went along with moderate symptoms of respiratory distress, until she succumbed to a complicating bronchopneumonia at 17 months of age. Necropsy revealed an enormous epithelium-lined cyst with a bronchiole entering it by a devious course through a network of identical microscopic chambers lying within the wall of the main cyst. The lung covered only one-half of the cyst surface.

Altmann observed a structurally similar formation in the lung of a female infant who died at the age of 3½ months with a diagnosis of pertussis bronchopneumonia. The right lower lobe contained a gas filled cyst, which, after fixation, measured 7 by 5.5 by 4.5 centimeters. Half of its upper surface lay immediately below the parietal pleura the remainder was in intimate association with the lung parenchyma. It had a thin wall with a smooth glistening inner aspect, and two semi-circular partitions on the posterior surface. A bronchiole the size of a small bristle communicated with the cyst.

Miller in 1926 described a large air containing cyst, as demonstrated by roentgenological and clinical signs, in a child 5 weeks old. There were severe attacks of dyspnea lasting from 15 to 30 minutes. At first the condition was thought to be a pneumothorax on the right side, displacing the mediastinum and heart to the left. Repeated thoracenteses released air under pressure, and gave temporary relief from the respiratory embarrassment. Later, a small rubber tube fitted with a one way valve which allowed the escape but prevented the aspiration of air was inserted into the cavity. Marked improvement occurred. After the air containing pocket had decreased greatly in size, the

tube was removed 2 weeks later the cyst was found to have regained its original volume. The child died at the age of 5 months apparently from asphyxia. No necropsy was performed.

Burghard (1926) described a large air distended cystic cavity in the left lung of a 2 months old infant who died of a terminal bronchopneumonia. Dyspnea had been present since 2 weeks of age. The cyst was found within the parenchyma of the lung which itself was emphysematous. The opposite lung was a little compressed and the mediastinum displaced to the right. The cavity communicated with the bronchial tree through a tiny bronchiole. Its wall was thin the microscopic structure was not reported.

Huenermann and Sievers (1930) describe a multiloculated cystic formation or "honeycomb lung" which filled the left chest of a 2 weeks old infant, causing dextroversion cordis and compression of the right lung. This was air containing when the infant was first seen. It rapidly increased in size and produced symptoms of cyanosis and dyspnea. Thoracocentesis removed air under pressure but gave no relief of symptoms. Death occurred at 3 weeks of age. The postmortem X ray film showed a left pneumothorax with the cystic left lung partially collapsed and clearly outlined. Necropsy demonstrated multiple distended air containing chambers within the left upper lobe. Several entering bronchioles were present.

A suggestion as to pathogenesis is ventured in the first three of the above reports and each author assumes that the large cystic chamber began as a small air containing bronchiectasis which dilated in postfetal life. Inasmuch as in all but one a large portion of the wall was situated subpleurally it would follow that in expanding the cyst must have torn its way peripherally through enveloping lung parenchyma within the short space of a few weeks. One would expect to find therefore as a consequence of the quick gigantic increase in size a greatly stretched thin walled capsule and a flattened lining with some areas of rupture. Instead however these cysts characteristically had the opposite structure with well developed columnar epithelial lining and thick fibromuscular capsules.

In our own case with a wall thinned in places this change was due to secondary ballooning with air after the fluid contents had been discharged.

Because of the similarity in gross appearance, age incidence and clinical behavior of the above air cysts to the later stages in our case it seems probable that they all had a

similar beginning i.e. from the rupture of a fluid containing cyst. Their well developed walls are consistent with this interpretation as is also the presence in each of an entering bronchiole. Rupture and evacuation must then have occurred soon after birth.

Swanson, Platou and Sadler in 1928 reported a solitary fluid containing cyst noted in an infant 7 weeks of age. There were frequent attacks of cyanosis and dyspnea and the right side of the chest showed impaired resonance and suppression of breath sounds. X ray examinations revealed a dense opaque area throughout the whole right side of the thorax with some areas of decreased density near the base. The heart and mediastinum were displaced to the left. After it was tapped the cyst refilled rapidly with prompt recurrence of symptoms. An open fistula was made surgically when the child was 3 months old and the cavity was irrigated repeatedly. In 2 months it decreased in volume from approximately 300 cubic centimeters to 8 cubic centimeters as measured by sodium iodide injections. There was no evidence of an open communication with a bronchus. The child died following a bronchoscopic examination. Cells of glandular tissue were found in the wall of the contracted cyst at necropsy.

This large fluid cyst occurred in an infant whose age was comparable with that of the cases of air cysts discussed. If rupture into a bronchus had occurred we believe it would have shown the X ray appearance and expansile behavior of the air cysts already described. Its clinical manifestations resembled closely that of our own case when first observed.

Several reports have been made of cysts structurally like those in the case of Huenermann and Sievers but containing fluid instead of air. These were found in stillborn fetuses or in infants living only a few hours. Wolman described a dilated fluid filled bronchiogenic cystic structure in the lungs of a 6 months stillborn fetus. Pappenheimer reported an identical cyst in an 8 months premature infant who lived only 3 hours. No communication with the bronchial tree could be demonstrated in either case. In Kessler's 6 months old fetus, cystic fluid filled lymphangectatic chambers ramified through the pulmonary framework. Grawitz also described a fluid filled cyst in the lung of a newborn. Obviously postnatal factors can be ruled out in these instances. It seems likely that many of the

cases reported as congenital bronchiectasis originated as similar cysts in fetal life.

It is necessary that all air containing cysts possess an outlet into the bronchial tree patent at intervals if not continually since otherwise the contained air would be absorbed in the course of time. In the group of large air cysts described all maintained their large volume and some increased in size, which indicated that air entered more rapidly than it was absorbed. It seems probable that the communicating bronchiole entering the cyst cavity by an angular tortuous course acted as a valve allowing entrance but preventing outflow of air. At each expiration air pressure within the cyst became raised temporarily above the external intrathoracic pressure with a resultant expansion and gradual stretching of the wall until the maximum size permitted by structural conditions of the lung and mediastinum was attained. As the cyst expanded labored breathing and cyanosis resulted just as would occur in massive pneumothorax and death ensued from asphyxia unless the process ceased spontaneously or was interrupted by surgical interference.

It is easy to understand why these expanding cysts are not encountered in older children and in adults. In premature and young infants, all tissues (37) including the pulmonary parenchyma are relatively weak, friable and poorly resistant to the strains of tension and other trauma. In our first patient a premature infant who was 31 weeks old at death the pulmonary elastic fibers which normally appear in the first or second month postpartum (19) had not yet developed.

If there is no valve action at the communicating bronchiole or if the location of the cyst is such that neighboring structures support it, or if a chronic infection has provided support by causing a deposition of fibrous tissue, the cyst may remain constant in size. The following case seems to support this view.

CASE 2: Non-expandible cyst. A premature female child was observed for 10 months at The Children's Memorial Hospital, during which period she had frequent bouts of fever, with cough and dyspnea, sufficient to require admittance to the wards on

four occasions. She was constantly undernourished, her greatest weight being 12 pounds 8 ounces. No physical signs of a cavity within the lung were elicited the most constant chest findings were impaired resonance and higher pitched breathing in the right lower lobe behind. Frequent roentgenological examinations during each period of hospital care showed a constant oval area of decreased density in the right lung at the cardiophrenic angle. The lateral border of the cavity was dense and the hilum markings above it were prominent presumably because of superimposed infection. Death from bronchopneumonia occurred at 35 months of age. Necropsy permission was not obtained. The diagnosis was chronic bronchitis and bronchopneumonia, congenital cyst of lung, congenital heart defect, bilateral cataract, malnutrition. We believe that the diagnosis of a congenital cyst, rather than a localized pneumothorax is favored by the contour of the air pocket, its location and failure to absorb and the associated presence of other anomalies. Steinmeyer (37) and Eloesser (9) have described somewhat similar cases.

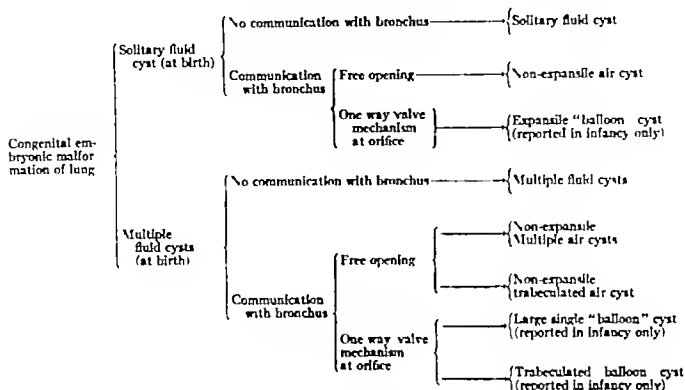

Based upon the above observations and discussion we venture the classification of lung cysts as shown in Table I.

DIAGNOSIS

Large cysts occurring in the lungs of infants produce first an increase in the respiratory rate and later cyanosis. If the cysts contain fluid there may be local dullness and absence of breath sounds, but if they are filled with air there is hyperresonance and the breath sounds are faint or high pitched. If marked displacement of the heart and mediastinum occurs, percussion dullness may appear over the normal lung as it becomes compressed. Large cysts may produce dyspnea difficulty in swallowing or cough and in extreme cases the chest may bulge. Small cysts may produce no symptoms at all or only those due to superimposed infection.

There appear to be no pathognomonic roentgenological characteristics of a fluid containing cyst but a large dense shadow surrounded by normal appearing lung tissue, in an otherwise quite healthy infant, should arouse suspicion of that condition. Contralateral displacement of the mediastinum is usually not, by itself a dependable sign. In infants an erroneous diagnosis of atelectasis is most likely to be made as occurred in the early stages of our Case 1. Aspiration of viscous fluid may be necessary to differentiate between

TABLE I—SUGGESTED CLASSIFICATION OF CONGENITAL LUNG CYSTS ON THE BASIS OF POSTNATAL BEHAVIOR

a fluid filled cyst and encapsulated fluid from other causes

Upon the roentgenological findings chiefly does the differentiation between positive pressure pneumothorax and balloon air cyst depend. In the latter the air containing cavity lies *within the lung* and enlarges as the gradual addition of trapped air by exerting a uniform outward pressure stretches the cyst wall and displaces the surrounding lung tissue around it in all directions. Consequently the lung tissue can be recognized upon the film as normal or varied densities at the apex, the costophrenic, and the cardiohepatic angles. The shadows of hilum structures on the mesial side of the lung field soon fade partly because of their migration about the surface of the cyst, but principally because of the early displacement of the easily movable mediastinal boundary of the lung contralaterally. In massive pneumothorax on the other hand the air lies in the pleural cavity separating the normal contact of the visceral and parietal pleura and exerting pressure from *without the lung* upon its entire pleural surface. This pressure produces collapse of the whole lung with displacement of the mediastinal struc-

tures to the opposite side. The lung parenchyma at the hilum is not thinned out nor are there the shadows of tissue at the apex and angles. A readily noticeable differentiating point is the retracted collapsed lower lobe in massive pneumothorax (Fig 15). Visualization of a dense curved line which assists in making a diagnosis of a cyst in the presence of other evidence must not be depended upon as a pathognomonic sign when occurring by itself, since adhesive bands as in pneumothorax following empyema may produce a somewhat similar appearance. A trabeculated cystic cavity may show as a network of thin densities on the film and may be confused with multiple bands of pleural adhesions. Here the history of a previous pneumonia or empyema supports the diagnosis of pneumothorax. It is significant that our Case 1 was called pneumothorax by all the members of the staff except one, who was familiar with the roentgenograms of a previous case of balloon cyst and noted the resemblance.

Massive pneumothorax, complicating a solitary cyst, aids rather than confuses the diagnosis if the pleural air happens to be

distributed so as to outline the contour of the collapsed cystic lobe. This point is beautifully demonstrated in the illustrations accompanying the report of Huenermann and Sievera.

Smaller air cysts are recognizable as rounded areas of decreased density with a smooth linear outline. When conditions permit radiopaque oil dropped into the bronchus may fill the cavity or may make its contour more clearly evident by filling the adjacent bronchial tree. The differentiation between a small air cyst and a localized pneumothorax (Figs. 12 and 13) may be difficult or even impossible at a single roentgen examination. Repeated observations, however, will usually show fixity in the case of a cyst and definite lability in a pneumothorax.

Bullous emphysema (Fig. 14) often appears as multiple air containing areas of decreased density upon the X ray film. In infants these are frequently secondary to irregular areas of atelectasis which show as increased densities. Successive examinations will usually demonstrate that the air containing spaces and the dense atelectatic portions fluctuate somewhat in density and relative size. There is also of course absence of a dense linear cyst wall.

True diaphragmatic hernia or eventration of the diaphragm (Fig. 16) with gas or fluid in the thoracic portion of the intestine or stomach can simulate roentgenologically as well as clinically solitary or multiple air or fluid containing cysts. Fluoroscopic examination, following the administration of oral barium, will demonstrate the misplaced stomach in the thorax and subsequent X ray films will outline the cyst-like loops of the herniated intestine.

Duken and Vollmer have each described a case of pneumatocele following pneumonia, in which a large air containing oval was found in the lung. Since these completely disappeared following a single aspiration we believe that a localized pneumothorax could better explain the findings. In our experience and that of Bigler (2) subpleural blebs do not attain a large size, and we have never been able to demonstrate them on the postmortem X ray films taken before the necropsy which reveals their presence.

Stein's (29) case reported as congenital pneumothorax was 1 week old when first observed and is 2½ years old now (30). The published films demonstrate a sharply outlined air pocket with pneumatic lung at the costophrenic angle a condition that is characteristic of large solitary cysts. We have, moreover, been unable to find a report of any case of congenital pneumothorax proved by necropsy.

A cyst filled with fluid usually presents a poorly defined margin, scarcely to be confused with the sharp borders of chondroma (13) ganglioneuroma (3) or echinococcus cyst.

TREATMENT

A thoracentesis was done in 4 cases of balloon cyst that were studied during life. Two were temporarily relieved (our Case 1 and Miller's patient). Another (Parnalee and Apfelbach's) collapsed during the procedure and was revived by artificial respiration the fourth (Huenermann and Siever's) developed a pneumothorax which hastened the exitus. A drainage tube with a valve allowing only the outlet of air gave effective relief for a few days to Miller's patient. A large fluid cyst in a small child (Swanson, Platou, and Sadler) was drained and became greatly reduced in size. While surgical removal of lung cysts has been successfully accomplished in adults, it has not been attempted in infants. It is hoped that through a greater knowledge of the pathogenesis and behavior of congenital lung cysts, recognition during life will occur more often and that a satisfactory treatment will eventually be devised to prevent the present high mortality in infants and young children.

SUMMARY

Two cases of lung cyst observed in infants are described. One of the cysts originated as a large lymphangiectatic fluid filled chamber which evacuated spontaneously and then ballooned out with air producing a fatal outcome. The other which was not verified by necropsy showed a constant X ray appearance over a long period.

Fluid cysts in infants, which are usually mistaken for atelectasis, do not have a char-

acteristic roentgenological appearance, but air containing lung tissue about an area of increased density should arouse suspicion of the presence of a cyst

The diagnosis of balloon cysts depends upon successive X ray and clinical studies and upon an understanding of the late stages of pathogenesis Usually an erroneous diagnosis of pneumothorax has been made The main roentgenological diagnostic points of a balloon cyst are the presence of lung tissue at the apex and angles and its absence at the usual hilum region A collapsed retracted lung shadow as in simple massive pneumothorax, is not seen on the film

Small air cysts which cannot be differentiated from other air pockets such as localized pneumothorax at a single examination will maintain a more or less constant appearance while the others will show changes and later disappear

Based upon a study of reported cases and of their own observation the authors believe that congenital air cysts of the lung are fluid containing at birth and that their postnatal behavior depends principally on mechanical factors A classification of congenital lung cysts is suggested

STUDIES IN PHYSIOLOGICAL AND PATHOLOGICAL UTERINE MUSCULATURE AT TERM

LEONARD ZWEIBEL, M.D. NEWARK, NEW JERSEY

From the I Gynecological Clinic, Vienna; Acting Chief of Clinic, Deutscher Dr. Kreis

UTERINE musculature at term presents a most interesting field for investigation yet there is very little to be found on the subject in medical literature. In order to appreciate the difference in the structure of normal and pathological uterine musculature such staining of the sections was utilized as to color the muscle fibers deep red and the connective tissue moderately deep blue. The staining method used for the preparation of the sections here presented is a modification of the axan method as described in Romels *Taschenbuch der mikroskopischen Technik* according to Heldenheim and Mallory but with shortening of the time of the staining with a marked increase in the tissue contrast. The following method was used.

The sections were prepared in paraffin. The slides were then deparaffinized by passing them through xylol, alcohol and water then into azocarmine¹ (muscle stain) and for 45 to 60 minutes kept in the incubator at 55 to 60 degrees centigrade removed from incubator and kept at room temperature for 5 to 10 minutes. (If the stain has been previously heated, the slides should be kept in the stain for only 15 minutes.) Following this, the sections were differentiated in alcohol aniline dye (1 cubic centimeter aniline oil to 1000 cubic centimeters of 90 per cent alcohol) for $\frac{1}{2}$ to 1 minute were stood in acetic acid alcohol solution (1 per cent acetic acid made in 90 per cent alcohol) for 3 to 4 minutes, and were then placed directly into 5 per cent aqueous phosphotungstic acid for 45 minutes and again washed with distilled water. The connective tissue was stained next by placing the slides in aniline blue orange² acetic acid for 45 minutes and again washed with dis-

tilled water following which they were differentiated in 90 per cent alcohol for a few minutes, in absolute alcohol xylol, and then mounted.

Careful studies in the arrangements of muscle fibers have been made by William Hunter in England Madame Boivin Deville and Helie in France Roederer Luschka, Henle Hoffman, Bayer Hofmeier and others in Germany but unfortunately their investigations have not led to uniform results.

The myometrium, a muscular coat, although composed of bundles of involuntary muscle arranged with little individual regularity may be considered as having an inner most circular layer a thick middle layer in which the bundles possess a general tendency toward figure-of-eight formation in a most irregular fashion of network of interlacing fibers, and a thin imperfect outer layer in which their course is for the most part longitudinal. However in the uterus there is really no uniform arrangement in layers such as circular or longitudinal as may be found in other organs. The interlacing and crossing muscle bundle in the thick middle layer is, according to Henle and Luschka, the main layer of the uterus and is a dense network of muscle fibers. This thick middle layer is distinguished by the intermuscular connective tissue being vascularized in all directions by blood vessels, and hence is known as the stratum vascular. This muscle layer is confined to the uterus except below where it becomes continuous with the muscle of the vaginal wall. The longitudinal muscle bundles of feeble outer layer which is present only over the fundus and body are continued beyond the uterus on to the tubes and into the broad, round, ovarian, and uterosacral ligaments.

The individual muscle cells are unstriated and of various shapes, usually elongated spindle shaped, or as rarely seen short and

¹Azocarmine B—0.15 per cent in 10 per cent plus 1 cubic centimeter glacial acetic acid and add up to 100 cubic centimeters water or see-cerum G—1 per cent heated for 1 minute plus 1 cubic centimeter glacial acetic acid and filter water.

²Aniline blue orange acetic acid—mix blue, 1.5 grams; gold orange G, 0.5 grams; water 100 cubic centimeters; glacial acetic acid 10 cubic centimeters—heat to boiling, cool and filter. Use dilute and with care.

Fig. 2 Uterus, cesarean section. Azan stain

broad. In a few instances striated muscle fibers have been found in the uterus post partum near the placental site. Their length varies from 0.040 to 0.060 millimeters. On transverse sections the cells usually appear round, ovoid or polygonal, somewhat like a red cell but with the less defined outline and in many cells the nucleus is not on the plane section. The nucleus in the long diameter of the cell is ordinarily rodlike, but if fixed during the contraction is sickle or half moon shaped.

During pregnancy the enlargement of the uterus is not symmetrical but is marked in the fundal region. This can be readily appreciated by observing the relative position of the infundibula of the fallopian tubes and the ovarian ligaments, which in the early months of pregnancy are almost on a level with the fundus, and in the latter months their attachments are found to point slightly above the middle of the organ. The increase in size and thickness of the walls of the uterus are brought about by combined hyperplasia and hypertrophy or increase in number of the individual muscle fibers. The position of the placenta also exerts a determining influence upon the extent of the hypertrophy; the portion of the uterus to which it is attached enlarging more rapidly than elsewhere, as is

clearly shown by the position of the uterine ends of the round ligaments which are close together when the placenta is inserted upon the posterior and far apart when it is upon the anterior wall. Postpartum the uterus is enlarged to a varying degree even if involution is complete. On section the musculature appears coarse and the blood vessels stand out

Fig. 3 Uterus, cesarean section. Postmortem. No labor

Fig. 4. Normal uterus postmortem. Azan stain.

Fig. 5. Placenta previa. Uterus, cesarean section. Azan stain.

above the surface. Microscopically there may be a preponderance of connective tissue and there is usually some lack of uniformity the involution being more advanced in some parts than in others.

In the uteri studied, the structure of the fibers was compared as to size, shape and staining ability, and the amount of connective tissue was carefully noted. The low power magnification only is demonstrated. The fibers were measured as to the number per millimeter and at least ten fields were counted on each preparation and the average taken to determine the width of the fibers. The length could not be calculated as accurately.

Figures 1 and 2 are sections from uteri removed after cesarean sections. The muscle fibers are heavy, very long and deep staining. There is very little intrafascicular connective tissue and a slightly greater amount of interfascicular connective tissue with an average of 22.4 to 30.5 fibers per millimeter respectively in the width.

Figure 3 is a section from a uterus, a cesarean section postmortem which was performed to get a living baby from a woman at term who was killed by a fall. She had had no labor pains. Here too the fibers appear to be very long and deep staining but thin. The intrafascicular and interfascicular connective tissue were both scant. The average width of the fibers is 36.7 fibers per millimeter.

Figure 4 is a normal postpartum uterus removed after death of the mother. The muscle fibers are very long and heavy as well as deeply staining. The transversely cut fibers are also very thick and there is barely enough intrafascicular connective tissue to be able to distinguish the individual fibers and there is a scant amount of interfascicular connective tissue. The average width of the fibers in this section is 25.4 fibers per millimeter. Figure 5 is a section from a uterus of a case of placenta previa. Here the musculature appears like that of the normal uteri removed after a cesarean section, and there is similar paucity of both intrafascicular and interfascicular connective tissue. The average width is 23.7 fibers per millimeter.

Figure 6 is that of a section of a uterus from a case of placenta accreta. The longitudinal fibers appear to be shorter and the transversely cut fibers smaller. There is not an equal staining throughout, many parts of fibers being only lightly stained. The average number of fibers per millimeter is 27.6 in their width. However, the number is proportionately greater because of a fair amount of intrafascicular connective tissue, with only a slight increase in interfascicular over the normal.

Figures 7 and 8 are two sections taken from the same organ, an atonic uterus, laboratory

Fig 7 Atonic uterus.

protocol number 22627 The patient was a young woman aged 19 years a primipara. Menses had started when she was 17 years of age. After a normal pregnancy she had had a normal delivery followed by a severe bleeding before the placenta was expressed and this had to be done by the Credé maneuver. The vagina and uterus were douched with warm saline, the uterus massaged and a tamponade inserted into the uterus. An intravenous normal saline infusion was given, followed by a blood transfusion. In spite of all these measures the bleeding continued and the patient died 2 hours after delivery. Postmortem examination showed hyperplasia of the thymus gland. The ovaries were markedly hypoplastic. The uterine wall appeared thin, the inner surface entirely smooth without any placental tissue present. Postmortem diagnosis: atonic uterus probably due to status thymicolymphaticus.

Atonia is also spoken of as exhaustion of the uterine muscle. The Duncan separation of the placenta is thought to be a result, in most instances of uterine exhaustion thus causing the incomplete separation of the placenta and with it, the severe bleeding postpartum. Such a uterus is very large and soft, the muscle being entirely without tonus. Status thymicolymphaticus as presented in the above

case history has never been mentioned by any of the authors as a probable cause of atonia. However such a case is prone to have hypoplastic ovaries and also a uterus which is not well developed and with poor musculature. Causes which have been cited as capable of producing uterine atonia are those producing exhaustion of the nervous mechanism governing the uterine mechanism such as prolonged labor, loss of blood from antepartum

Fig 8 Atonic uterus.

hemorrhage emotional causes, improper co-ordination of the powers mental and nervous depression from severe pain anxiety or shock. Antonia due to any of the above causes is aggravated by toxemias of pregnancy Uteri which are characterized during labor by cramp-like pains accompanied by very weak contractions uteri which are affected by fibroids or uteri overdistended by polyhydramnios or multiple pregnancies almost always tend to be flabby postpartum

In Figures 7 and 8 the pathology of the fibers can be readily seen The fibers are thin and short and have not a very good affinity for the stain In some areas there is a slight amount and in other areas a vast amount of intrafascicular connective tissue but a very marked amount of interfascicular connective tissue is to be seen throughout The average number of fibers in Figure 7 was 52.2 fibers and on another checking was found to be 52.5 fibers per millimeter In Figure 8 the average number of fibers was 53.7 and another check ing was 54.2 per millimeter

TABULATED SUMMARY

Fig	Average number fibers (width) per mm	General characteristics		Amount of connective tissue	
		Length of fibers	Affinity of fibers for stain	Intrafascicular	Interfascicular
		Long	Good	Very little	Moderate
	20.5	Long	Good	Very little	Moderate
3	26.7	Long	Good	Very little	Scant
4		Long	Good	Very little	Scant
	7	Long	Good	Very little	Scant
6	27.6	Shorter	Fair	Much	Slightly greater than normal
7	52.2 52.5	Very short	Poor	Moderate	Much
8	53.7 54	Very short	Poor	Moderate	Much

The above tabulated summary gives in brief the important findings in the various types of uteri studied normal uteri removed following caesarean section, normal uteri post partum a uterus removed in a postmortem caesarean section without labor uterus with placenta praevia, a uterus with placenta accreta, and an atonic uterus. The points com

pared are the number of fibers per millimeter the relative lengths of the fibers and their staining ability and the amount of intrafascicular and interfascicular connective tissue

Special thanks and gratitude are due Professor Doctor Oskar Frankl for allowing me free use of the material at his clinic and also for his invaluable advice

CLINICAL SURGERY

FROM THE SURGICAL SERVICES, MASSACHUSETTS GENERAL HOSPITAL

A NEW MUSCLE SPLITTING INCISION FOR RESECTION OF THE UPPER THORACIC SYMPATHETIC GANGLIA

JAMES C. WHITE, M.D., F.A.C.S., REGINALD H. SMITHWICK, M.D., F.A.C.S., ARTHUR W. ALLEN, M.D., F.A.C.S., and WILLIAM JASON MIXTER, M.D., F.A.C.S., BOSTON, MASSACHUSETTS

SINCE 1929 the writers have performed 52 resections of the upper thoracic sympathetic ganglia through the posterior thoracic route which was first suggested by Henry on anatomical grounds for the relief of angina pectoris in 1922 and later modified and first performed by Adson who made it the standard operation for the relief of vasospasm in the upper extremity. In the beginning we performed the operation just as Adson described it but with increasing experience we have adopted a new type of skin and muscle incision. We believe that this new modification makes for a more anatomical type of incision that it gives a better exposure of the first or second rib and that it obviates certain postoperative complications which will be discussed below. We have performed this operation for a variety of peripheral vascular and other conditions which have been described in previous communications (6, 7, 8, 9). It is not therefore our object to discuss the indications for or the results of thoracic ganglionectomy at this time but to describe in detail the technique which we have found most satisfactory.

In the first 34 cases of this series a longitudinal incision was made in the skin exactly as described in Adson's papers (1, 2) for a bilateral sympathetic ganglionectomy; the incision was made in the midline from the spinous process of the seventh cervical vertebra down to the fourth or fifth thoracic; in the case of a unilateral resection a similar paramedian incision was made one to two fingerbreadths lateral to these spinous processes. With this approach one is forced to divide the trapezius muscle as well as the rhomboids and the serratus posterior superior directly across their fibers. We believe that such an incision is unanatomical because it produces considerable bleeding and also because muscles cut in this direction are difficult to heal. Furthermore in

using this approach it is necessary to employ prolonged forceful retraction of the muscles in order to expose and resect the first or second ribs. Such retraction traumatizes delicate muscle fibers and deprives them of their blood supply during the ensuing period of the operation. These factors plus the use of small rubber drains in some cases, were the cause of sepsis in 29.4 per cent of the incisions made by this approach. Sepsis of this type, while never serious, lengthened the hospital stay of these patients from 1 to 3 weeks and frequently resulted in the separation of the sutured muscles with an unsightly scar and weakness of the shoulder girdle.

In considering the best method of obviating these complications the writers' attention was directed by Dr. E. D. Churchill to an incision recommended by Head and Bigger for extra pleural thorocoplasties of the upper three ribs.¹ We have now utilized this approach in 18 cases with only one instance of wound sepsis which occurred in an epileptic who tore open his wound during a convulsion. All the wounds have healed with perfect apposition of the muscles which have only been divided in the plane of their fibers. Such a muscle splitting incision can be carried out with very little bleeding and the minimum of trauma to the muscles. Exposure of the first or second ribs is also facilitated by the direction of the incision as it parallels their course; furthermore a minimum of retraction is necessary. When the skin muscle incision has been made, resection of the proximal portion of the rib with its transverse process and exposure of the sympathetic ganglia is carried out in exactly the same way as in the operation which has been described by Adson.

¹Since this paper has been in preparation Dr. E. C. Harvey and Dr. A. W. Ouchterlony, of New Haven, have informed us that they have also developed a similar oblique incision from the suggestions of Head and Bigger.

Fig. 1 The insert shows position of patient on cerebellar table. Note that three pillows under thorax and low position of head-rest give good flexion of cervicodorsal spine. The inner sides of elbows and arms should be well padded to avoid pressure paralysis. The skin incision and separation of trapezius muscle fibers are shown. The insert also shows the orientation of the incision in the following drawings.

Fig. 2 The separated edges of the trapezius muscle are drawn back. The minor rhomboid has been separated from the levator anguli scapulae muscle, while the foriceps grasp one edge of the serratus posterior superior which is being split by the scissors.

TECHNIQUE OF OBLIQUE MUSCLE SPLITTING INCISION

The patient is anesthetized with nitrous oxide, oxygen and ether administered by a closed pressure apparatus to enable the lung to be expanded in case the pleura is opened. Intratracheal anesthesia is the ideal method if an anesthetist is available who is accustomed to its administration. Under these circumstances we advise avertin (tribromethyl alcohol) supplemented with nitrous gas, oxygen and ether. The patient should be

placed on a cerebellar type of operating table with the forward curvature of the head and neck exaggerated by placing three pillows under the chest (Fig. 1). This position serves to spread the upper intercostal spaces and to give the greatest possible abduction to the scapula. The skin incision is made starting a finger's breadth lateral to the spinous process of the seventh cervical vertebra and running obliquely downward and outward over the medial angle of the scapula. This incision need not be over 8 centimeters long. In the

Fig. 3. All the muscles attached to the scapula have been retracted. The second rib shows in the lateral half of the field, whereas medially the rib and its transverse process are covered by the longitudinal band of the erector spinae group of muscles.

Fig. 4. Exposure of second rib after separation of intercostal muscles and underlying pleura. Note articulation with transverse process, which must also be removed. The first and third ribs barely show in the upper and lower edges of the incision, but by suitable mobilization and retraction of the muscles they can be adequately exposed and resected.

case of a bilateral operation, a similar incision is made on the opposite side but it is unnecessary to carry it across the midline. The cut is carried down to the deep fascia, bleeding points are ligated, and skin towels are applied. This oblique

incision runs nearly parallel to the fibers of the trapezius which are now separated by cutting through the fascia and stretching with the fingers. The fibers of the trapezius are then retracted upward and downward, thus exposing the minor

Fig. 5. Cross section of the thorax at the level of the second thoracic vertebra, to show the position of the sympathetic trunk.

rhomboid and levator anguli scapulae muscles (Fig. 2). Separation of these is again carried out by blunt dissection and the muscles then drawn apart by a pair of retractors. At this stage the upper ribs can be palpated, being covered only by the thin fibers of the serratus posterior superior muscle (Fig. 3). On splitting its fibers, the three upper ribs and the deep longitudinal back muscles are exposed. The attachments of these deep muscles are then separated from the transverse processes of the first and second ribs and drawn back by a medial retractor (Fig. 4). The resulting exposure gives ample room for resection of the proximal portions of any of the three upper ribs. Generally speaking we intend to remove a portion of the cervicothoracic sympathetic trunk extending from above the inferior cervical ganglion to below the second thoracic ganglion. It is easier to reach the upper portion of the trunk through the first rib and the lower portion of the trunk through the second rib. However, as a rule this portion of the trunk can be resected through either rib. Occasionally in difficult cases, it is best to remove both.

It is important that at least the proximal 3 centimeters of the rib and the entire transverse process should be removed. The greatest care should be exercised to leave the pleura intact, but if a small opening is made it can frequently be closed by a small piece of muscle and the lung maintained in an expanded position by warning

the anesthetist to use positive pressure. As a general rule the patient's condition does not change but it is of the greatest importance to remember that certain types of opening in the pleura can allow more air to enter on inspiration than can leave on expiration. Even with adequate means of controlling the intratracheal pressure the operator must be constantly on his guard against such a valve type of opening and be ready to aspirate air from the chest if the patient's blood pressure falls or cyanosis develops. If the operator is on his guard the air can easily be removed with a large syringe and needle or through a rubber catheter inserted through the hole in the pleura and connected to the suction apparatus. Such a device should be always at hand. One of the writers had a case of sudden collapse from this cause in which over a liter of air was removed from the pleural cavity and the patient's condition immediately improved. Had this not been foreseen the patient surely would have died on the table.

After removal of the rib and transverse process, the pleura is separated from the body of the vertebra with blunt dissection. For this purpose, the operator's index finger is the ideal instrument. The pleura must be separated to a depth of 3 centimeters and can best be retracted by the use of a brain spoon. The best possible illumination is a requisite for this part of the operation. At this depth the sympathetic chain is usually seen run-

Fig 6 Nerve structures seen after resection of second rib and transverse process.

Fig 7 Nerve structures seen after resection of first rib and transverse process. The cervicothoracic ganglion lies at a greater depth than is shown here, where it is depicted drawn up into the wound in order to show its shape and the relation of its ram.

ning longitudinally and adherent to the sides of the vertebral bodies. If it cannot be located in this way it can be found by search for the sympathetic ramus which leave the second intercostal nerve and join the sympathetic trunk about a centimeter deeper down (Fig 5). The communicant ramus of the large first thoracic nerve, which crosses the upper end of the incision, can also be used as a guide to find the sympathetic trunk, as the first thoracic ganglion lies just beneath it. Once the trunk is located, it should be drawn up on a nerve hook and followed both upward and downward by a blunt dissection (Fig 6). Through

either a first or second rib resection it is possible with care and patience to follow the trunk downward and cut it beneath the small second thoracic ganglion. Then with downward traction and by successive cutting of the small sympathetic ramus as they leave the trunk, it should be possible to visualize two large ganglia higher up (Fig 7). In our experience the stellate ganglion has usually consisted of two large and distinct components, the lower and smaller of the two lying just beneath the large first thoracic nerve, the second and larger ganglion about a centimeter above. Rarely these two ganglia may be fused into a single struc-

Fig. 8. Relation of the left cervicothoracic ganglion to the large arteries of the upper thorax. The descending branch of the costocervical artery which forms the first and second intercostals, may be either superficial or deep to the sympathetic trunk. The upper end of the inferior cervical ganglion lies on the vertebral artery. The subclavian lies considerably deeper and is not likely to be seen unless the pleura is widely reflected.

ture. It is well to appreciate that the inferior cervical and upper thoracic ganglia vary greatly in size, shape, and position, and that in no two cases are these structures identical. A large ramus usually joins the first thoracic ganglion to its spinal nerve, but occasionally the ganglion and nerve are fused (a condition we have encountered in 3 of our cases). For this reason it is extremely important to have a good exposure in order to avoid injury to the first thoracic nerve with resultant partial paralysis to the arm. Even handling of this nerve should be avoided as much as possible, as this is a frequent cause of severe postoperative neuritis in the upper extremity. It is also necessary to remember that the cervicothoracic ganglion is in close relation to the large costocervical and vertebral arteries and to a lesser degree to the subclavian arteries (Fig. 8). Minor bleeding in this region is easily controlled by the use of dura clips, but an injury to the vertebral artery in this region would cause severe hemorrhage. After the large ramus joining the first thoracic ganglion to its spinal nerve is cut, it is not difficult to draw the sympathetic trunk downward to a point where the inferior cervical ganglion can be safely dissected out.

The incision is closed tightly unless persistent oozing demands drainage. Otherwise we have found drains to be unnecessary and a frequent

Fig. 9. Scars of bilateral incisions. From a photograph taken 14 days after operation on the right side, 7 days after operation on the left.

cause of infection. As the retractors are removed, the muscle edges fall together and require only a few interrupted catgut sutures for perfect apposition. A row of interrupted sutures through the deep fascia of the trapezius, and silk sutures in the skin, complete the operation. The best dressing consists in silver foil covered with gauze sponges, which are held in place by crucial strips of adhesive running over the shoulder.

In this operation postoperative shock almost never occurs unless an extensive pneumothorax is allowed to develop through opening the pleura. Such an accident can usually be avoided by taking sufficient time in resecting the rib (especially in the second rib approach), and in using careful, slow blunt separation of the pleura from the bodies of the vertebrae. Even if a pneumothorax occurs, serious complications can be avoided by its early recognition and thorough aspiration of the air. Although the patient usually shows no change in blood pressure or pulse rate, we have felt that even under the most favorable circumstances the bilateral operation should be done in two stages. With the oblique muscle splitting incision, all skin sutures can be removed within a week and the operation performed on the opposite side at the end of this interval. As neither incision is carried to the midline, the previous scar can be completely covered with the skin towels at the time of the second operation. Postoperative discomfort lasts only a few days and the patients need not be kept in bed over a week. The usual appearance of the bilateral incisions, 7 and 14 days after operation, is shown in Figure 9.

SUMMARY AND CONCLUSIONS

As the result of the recent growth in understanding of the sympathetic nervous system the

more accurate knowledge of the ganglia which must be removed to produce a given effect and the development of improved diagnostic methods the indications for thoracic sympathectomy have been greatly enlarged. The increasing importance of this procedure has led us to report a new oblique muscle splitting incision which in our hands has avoided much unnecessary bleeding and trauma of the large muscles of the back. As the result of this slight technical improvement, wound healing has been greatly accelerated, sepsis and separation of the divided muscles has been practically eliminated and access to the upper ribs and their underlying ganglia has been facilitated.

FROM THE UNIVERSITY OF MICHIGAN HOSPITAL

TOTAL PULMONARY LOBECTOMY¹

A SIMPLE AND EFFECTIVE TWO STAGE TECHNIQUE

JOHN ALEXANDER, M.D. F.A.C.S., ANN ARBOR, MICHIGAN

CERTAIN cases of bronchiectasis and multiple pulmonary abscess can be cured only by total removal of a lobe of the lung. The exceptional difficulty of the technical problems connected with total lobectomy is evidenced by a 53.4 per cent mortality in 127 cases that I have collected from the clinics that have not been importantly connected with the relatively recent advances in technique. Another series of 115 cases with a mortality of 21.5 per cent has been collected from the four clinics in the United States and the four in Canada and Europe that have been chiefly responsible for the present hopeful outlook for a steadily declining mortality rate and an increasing proportion of truly complete cures.

The present justifiable optimism is especially gratifying in view of the statements made by Samuel Robinson (26) in the presidential address before the 1922 meeting of the American Association for Thoracic Surgery. He said, after presenting what is undoubtedly one of the most pessimistic descriptions of the difficulties of an operation that has ever appeared in print that "It has always been my belief that the greatest triumph in thoracic surgery will be the surgical eradication of this deplorable disease (bronchiectasis). Tuffier in 1924 said that he had never completely cured a case of pure bronchiectasis. Archibald in 1927 wrote that the problem of lobectomy is chiefly concerned with the question of operative mortality and that it will be solved when the mortality has been reduced to 20 per cent or even less.

In this article I shall consider critically the various techniques that appear on the basis of results and theory to have the greatest promise. I shall present in detail a simple operation that seems to me to make more effective use than does any other of safeguards against the complications of shock, primary and secondary hemorrhage, pneumonia, overwhelming infection of the pleura and mediastinum, mediastinal emphysema, bacteremia, tension pneumothorax and mediastinal "flutter" which have been the chief reported causes of death after lobectomy.

Briefly, this operation consists, at the first stage in resection of the posterior portions of the sixth, seventh, and eighth ribs, separation of the dis-

eased lobe from any pleural adhesions, gentle stroking with gauze of the parietal and visceral pleura of the whole hemithorax in order to create a protective inflammatory barrier against subsequent infection and to cause the undiseased lobe to become adherent and the placing of an air-tight drain. At the second stage 9 to 12 days later, the incision is reopened, only the diseased lobe is freed from its new adhesions and the hilum of the lung is tightly ligated with silk and a rubber tube and the lobe is left in place until it comes away spontaneously. The incision is closed temporarily or if the mediastinum is rigid it is left wide open.

I have personally performed 18 total lobectomies with 3 deaths (16.6 per cent). Two of these operations were performed early in my experience by a technique (one stage in the presence of a non-adherent undiseased lobe) that I soon learned to consider as unsound and one of the patients died. The remaining 16 had adhesions over both the diseased and undiseased lobes at the time the lobectomy phase of the operation was carried out and 2 (12.5 per cent) died. Twelve patients (Table I) had few or no adhesions over the undiseased lobe at the time of the first of a two stage operation performed according to the most important of the principles that will be discussed, and 2 (16.6 per cent) died. Only the last 6 of these 12 received in more or less full measure the benefits of the operative technique that has finally been developed and none of them died. The results can now be judged in 11 of the 12 patients, all of the 9 living patients (81.8 per cent) are either completely cured or improved.

INDICATIONS

This article is concerned with total lobectomy as indicated for the common central type of bronchiectasis or for extensive multiple pulmonary abscesses, perhaps associated with bronchiectasis, and without inseparable pleural adhesions. It should also be useful for pulmonary neoplasms that do not require complete resection of the lobar bronchus for those that do I believe that the technique to be described by Churchill (12) is better.

Consideration will not be given to partial lobectomy as indicated for extracental cavernous

¹From the Department of Surgery, University of Michigan and the University Hospital.

lesions involving the parenchyma and bronch. There are frequently extensive pleural adhesions over such lesions and in this type of suppuration I have found the Fovats Graham partial cautery lobectomy to be of great value. Graham (5) has used this operation in 54 patients with only 6 operative deaths (11 per cent). The partial lobectomy advocated by Brauer seems to me less safe.

Elsewhere Alexander and Buckingham have discussed somewhat fully the management of various types and phases of non tuberculous pulmonary suppuration and considered the indications for total lobectomy. Briefly the patient and particularly his cardiocirculatory system must be in reasonably good condition and his disease should be known to be confined to one lobe as determined by lipiodol roentgenograms of all five lobes. In 4 of the 18 cases reported in this article lateral and anteroposterior bronchograms in which lipiodol appeared to have entered the upper as well as the lower lobe seemed to indicate that the lesions were confined to the lower lobe and yet, after basal lobectomy, additional bronchograms showed that there remained bronchiectasis in the upper lobe. This diagnostic mistake was occasioned by either of two errors: (1) Bronchiectasis which appeared in the postero-anterior bronchogram only as high as the fourth rib posteriorly was interpreted as occupying the apex of the lower lobe whereas it was actually in the mid portion of the upper lobe. The lateral bronchograms were of relatively little value at this high level. (2) Bronchiectasis which appeared in the lateral bronchogram in the left lower midaxillary line was interpreted as occupying the anterior portion of the lower lobe whereas it actually occupied the lingula of the upper lobe (first ventral branch of the upper lobe bronchus). The corresponding involvement on the right side is of the middle lobe and is more readily diagnosed in a lateral bronchogram.

Certain therapeutic measures should be given adequate trial for months or even a year or more, before a decision is made to perform a lobectomy. Most important among these are phrenicectomy (perhaps temporary phrenic nerve interruption is preferable, as suggested by Churchill (11) a modified sanatorium regimen postural drainage every 2 or 3 hours during the patient's waking hours, conservative treatment of sinus ear and mouth infections, one or more courses of bronchoscopic aspirations and possibly intravenous neosalvarsan injections. Some or all of these measures were used in each of the cases reported in this article before a decision to perform a lobectomy was reached.

Fig. 1. Indicating extent of ribs resected for basal lobectomy and relation of operative window to hilum of lung. Inset shows position of incision.

THE OPERATION

Pre-operative management. In the technique about to be described it is important that the sixth, seventh and eighth ribs be exactly identified for resection because they immediately overlie the hilum of the lung. It is therefore necessary to know before the operation is begun whether the lowest rib that is palpable in the loin is the eleventh or the twelfth so that a beginning may be made for an accurate count upward. This knowledge may be got either from a roentgenogram that shows all of the ribs or by counting the ribs, before the patient is draped downward from the readily identified second opposite the angle of Louis.

Shortly before operation the patient empties his lung of secretions as completely as possible. A small dose of pantopon or morphine without atropine is given before operation.

The patient is placed on his good side on the operating table in not less than 15 degrees Trendelenburg position. I rely upon this position and occasional aspiration of secretions from the mouth rather than upon intratracheal aspiration through a tube which, I believe dams back some of the secretions at the rima glottidis. The Trendelenburg position helps the secretions to gravitate toward the mouth and light doses of morphine and nitrous oxide do not abolish the cough reflex. These important precautions reduce the chance of postoperative pneumonia, this complication occurred only once among my patients and in that instance was not fatal.

Fig. 2 Simple encircling ligature of hilum of lower lobe is about to be tied close to pericardium. This is done by touch because even the partially deflated lobe obscures the hilum. For clarity the drawing shows the lobular pulmonary markings and the layers of the wound in the thoracic wall. Actually these are hidden at this stage of the operation by the traumatic inflammatory reaction produced by the first operation.

First stage Local anesthesia is used until the pleural cavity has been opened, and then light positive pressure nitrous-oxide-oxygen is given through a snugly fitting mask. The incision for the usual basal lobe lobectomy is made from the angles of the fifth to the ninth ribs and then over the eighth intercostal space to the posterior axillary line (Fig. 1). If the cutaneous incision is made more posteriorly the sacrospinalis muscle will be left bare after the second stage. The sixth, seventh and eighth ribs and the sixth and seventh intercostal bundles are resected from the very tips of the vertebral transverse processes to the posterior axillary line. The parietal pleura is widely incised and if pleural adhesions over the diseased lobe seem probably separable the bare sheet of parietal pleura is cut completely away between the fifth and ninth ribs and between the transverse processes and the posterior axillary line, so as to give free access to the lung. Its retention would serve no purpose. Rib spreaders are placed.

It is not possible to tell before operation how extensive pleural adhesions are unless a pneumothorax is induced and this is usually inadvisable (yet Brunn (8) has found it advantageous in ex-

pulling secretions before a lobectomy operation) because of the danger of a complicating empyema. Furthermore a pneumothorax would be unable to show whether or not adhesions, if present, might be separated surgically. The diseased lobe of my last patient was completely invested in adhesions, most of which were broken without difficulty by the fingers. The fingers are used to rupture only such delicate adhesions as would not cause even tiny tears in the lung with possible resulting pleural infection, which would certainly be a grave complication at this stage. Adhesions in the interlobar fissure are usually firmest at its costal surface and I have found it useful to open the fissure sufficiently to admit a finger into the interlobar space; the finger can usually easily separate the lobes up to the adhesions between them at their costal surfaces and these may then be divided accurately and quickly with scissors. Scissors should be used to divide other tough adhesions which are frequently met in the costovertebral gutter and between the lung and diaphragm and occasionally between the lung and pericardium. The upper lobe is usually free of adhesions. If as occasionally happens, the adhesions investing the diseased lobe are very tough and extensive and their division is difficult and slow I believe that the operation should be abandoned and Graham's cantury pneumonectomy resorted to. I lost a patient because of unwisely attempting to divide such adhesions.

The free edge of the pulmonary ligament should be divided with scissors and the rest of the ligament safely torn with a finger up to the inferior pulmonary vein. The less accessible portions of the pleural cavity may be better exposed by very gently retracting part of the lobe held by one or two Duval pulmonary forceps which occlude working space far less than a retracting hand.

In bronchiectasis of the large central bronchi without complicating infection and induration of the pulmonary parenchyma, the diseased lobe may be soft and have a normal appearance. In fact, a distinguished thoracic surgeon has reported that this phenomenon once so confused him that he mistook the diaphragm for the diseased lobe (which was non-adherent) and began to dissect it from the thoracic wall before he discovered his mistake. On the contrary fibrous pneumonia may cause such shrinkage of the lobe and compensatory emphysema of the neighboring lobe or lobes may so cover the diseased lobe, that its identification may be momentarily difficult.

The next step in the operation is very gentle stroking of every portion of the mediastinal, costal, diaphragmatic, and visceral (except that of the

Fig. 3. About 3 weeks after total basal lobectomy in 5 year-old boy. At right, detail of wound. The great pleural hole that was occupied by the lobe has rapidly decreased by expansion of upper lobe, rise of diaphragm (q v) and slightly by displacement of mediastinum. Two bronchial mouths are plainly visible. The small opening below the main wound is where air tight drainage tube had been placed at bottom of costophrenic sinus, which has now become obliterated by adhesions.

diseased lobe) pleura with dry gauze held on the fingers. Especial attention should be paid to the region of the hilum and to the visceral and parietal pleura of the undiseased lobe. The dome of the pleura may easily be reached through the operative wound.

Three objects of paramount importance are attained by stroking the pleura

1. A sterile traumatic inflammatory exudate is produced on and under the pleura which exudate serves as a protective barrier against the infection that will inevitably occur within the pleural cavity after the second stage of the operation. This barrier tends to prevent the virulent phlegmonous type of pleural infection which may be complicated by mediastinitis and septicaemia, that has occurred with fatal results in so many reported cases of lobectomy in which the highly virulent organisms of the bronchiectatic secretions have been allowed to come in contact with a wholly or inadequately prepared pleura. Everts Graham, in 1923 recognized the importance of creating a leucocytic wall in the mediastinal pleura and of causing the undiseased lobe to become adherent before the diseased lobe was removed he used Robinson's gauze packing around the diseased lobe and left a clamp on the hilum for 3 or 4 days after the lobe was resected but apparently he was dissatisfied with the method and abandoned it.

Fig. 4. Boy 5 years old, after solid closure of wound following total basal lobectomy 6 months ago. Incision below main scar was made to obtain pedicled latissimus dorsi graft to close bronchial fistula. Dotted lines in lateral view represent original outlines of lower lobe.

2. During the 10 or 12 days that intervene between the first and second stages of the operation the traumatic pleuritis results in firm adhesion between the entire lung and its investing parietal pleura. At 10 or 12 days these adhesions are not so well organized as to prevent manual separation of the diseased lobe for the purpose of the operation and yet they are sufficiently firm to hold the undiseased lobe snugly to the thoracic wall. This fixation of the undiseased lobe limits the empyema that develops after the second stage to one half of the pleural cavity and thus empyema cavity becomes obliterated spontaneously. If the empyema should occupy the entire pleural cavity, as it does after a one stage lobectomy in the presence of a non-adherent undiseased lobe if pleural infection occurs, it would be a grave and perhaps fatal complication, especially in view of the large bronchial fistula that is usually present after removal of the lobe. Such an empyema is not likely to become cured spontaneously and may eventually require

rise of paralyzed hemidiaphragm and slightly by displacement of mediastinum and depression of soft parts into defect left by removal of posterior portions of sixth, seventh, and eighth ribs. Arrows on postero-anterior exposure indicate the medial ridge of the closed thoracic wall defect and the arrows on the lateral exposure indicate the risen diaphragm.

extensive, dangerous, and deforming Schede thoracoplastic operations.

3. A vitally important effect of having caused firm adhesion between the undiseased lobe and thoracic wall is stabilization of the mediastinum, which is contributed to by the stiffening of its pleura and subpleural tissues that follows gauze stroking of the mediastinal pleura. Stabilization of the mediastinum prevents the mediastinal shift to the opposite side and the flutter that have been responsible for the fatal outcome of so many reported lobectomies.

I feel that the method I have just described for treating the pleurae is the chief cause of the success of my lobectomies. It is the outcome of a series of experiments that I performed on 16 dogs in 1921. I was stimulated to carry out this work by reading the sound opinions published by Samuel Robinson in 1917 and by a letter received from him in February, 1921, in which he encouraged me to try to find a solution to the pleural problems.

From these experiments I found that the most effective method that I used to cause pleural adhesions was by rubbing the pleurae with gauze and lightly scratching them with the tip of a needle or scalpel. This sometimes caused traumatic pneumonia and sometimes the scratching allowed air to escape from the lung which would have been dangerous if the lung were severely infected. In man, therefore, I did not scarify and instead of

rubbing the pleurae I gently stroked them and no pneumonia or pleural infection have resulted (except the contralateral non-fatal case already cited). In dogs I found that neither pneumonectomy or treatment of the pleurae with such chemicals as tincture of iodine, 0.5 per cent silver nitrate, 20 per cent Sudan III in liquid paraffin, and ether was satisfactory. For example, in one dog 7.5 cubic centimeters of 7.5 per cent tincture of iodine introduced into one open pleural cavity caused death in less than 1 minute from what appeared to be true pleural shock. In another dog 5 cubic centimeters caused death in 11 days from a violent pleuritis and pulmonary congestion and edema. Three cubic centimeters of 0.5 per cent silver nitrate caused death in about 22 hours from a hemorrhagic pleuritis and congestion and edema of the lungs. Because of such results as these I feel that gently stroking the pleurae is safer than the use of chemicals, although it is true that the amounts used were relatively greater than would be used in man and that a dog's lung is more delicate than a man's. Lillenthal in his book published in 1925 described roughing the pleurae with gauze and painting with tincture of iodine but found that firmer adhesions were formed if iodoform gauze strips were laid over the undiseased lobe and withdrawn 48 hours later. Robinson (23, 24) attempted with only partial success to obtain mediastinal adhesions and fixation by packing

gauze around the diseased lobe at the second stage of a three stage operation, if the patient's condition made completion of the operation in two stages inadvisable. Everts Graham (16) used the same method.

Stroking the pleura with gauze causes a traumatic effusion, totaling from 400 to 1000 cubic centimeters or more, which must be aspirated several times during the following week. If tube drainage is not used. Some of the fluid often becomes encapsulated in various portions of the pleural cavity and, therefore is not removed by thoracocentesis in one place. If one of the pockets is between the undiseased upper lobe and the thoracic wall and is opened at the time of the second stage operation a partial upper thoracic empyema results and complicates convalescence. Therefore, in order to provide constant rather than intermittent, drainage for the effusion that forms and for whatever air may have been trapped in the pleural cavity as the wound was closed I shall in my next patient (in the past I have used drainage only after the second stage) introduce a fenestrated rubber tube 10 centimeters into the pleural cavity through the intercostal space that lies over the bottom of the posterior costophrenic sinus and couple this tube with a long tube whose free end will be kept anchored beneath sterile solution in a bottle under the patient's bed. So that this drainage system will remain absolutely air tight until several days after the second stage of the operation the tube should be introduced through the thoracic wall by making a stab wound no wider than the diameter of the tube, after the skin and extracostal muscles have been pushed far upward. The tube should be drawn through the stab wound by a haemostat and when the extracostal soft parts slip down over the tube this will then pass quite obliquely through the thoracic wall, thereby importantly helping to prevent sucking of air into the thorax around the tube.

The next step in the operation is to close the latissimus dorsi and rhomboideus major muscles with an interrupted continuous stitch of No. 1 chromic catgut, and the skin with interrupted silk without direct drainage of the wound. Just before the last knot of the muscle stitch is tied the anaesthetist completely expands the lung by raising the gas pressure. A vaselined dressing is placed and the incision is well supported by an elastikon dressing.

As the patient awakes from the gas anaesthetic he is made to expectorate all loose secretions from his mouth and tracheobronchial tree before he is changed from the Trendelenburg position on the operating table.

The systolic blood pressure increased during the operation an average of 21 millimeters in all of the patients operated on according to approximately this technique except that in 2 patients it dropped 28 and 20 millimeters. There was an average increase in pulse during the operation of 14.3 beats per minute. The average complete operating time was 63 minutes.

Postoperative management (first stage) Such doses of opiates should be used as to relieve pain sufficiently to make the patient willing to cough and yet not large enough to abolish his cough reflex.

Postural drainage should be continued throughout the interval between stages and should be begun within 2 or 3 hours after operation, and inhalations of carbon dioxide and oxygen should be given if needed to aid coughing and expectorating. Occasionally I have used postural drainage immediately after operation by placing the operating table in full Trendelenburg position or by inverting the patient over the edge of the table if he is unable voluntarily to expectorate his loose secretions.

Following operation the blood pressure is usually well maintained, but for several days the pulse is likely to be rapid, and occasionally is as high as 148 and even 158 and the respiratory rate is usually moderately increased. The temperature does not reach 101 degrees and as a rule is considerably less. Usually my patients get out of bed for a few minutes 8 or 10 days after operation.

The second stage should be performed 9, 10, 11 or 12 days after the first stage. If performed sooner than 9 days the pleural adhesions of the undiseased lobe are not likely to be strong enough to keep this lobe from retracting from the thoracic wall, whereas after 12 days the adhesions of the diseased lobe may be too tough to permit their rupture by the operator's fingers. If 3 or even 4 weeks were allowed to elapse between stages, instead of 10 or 12 days, the pleura would be still thicker and a correspondingly more effective barrier would exist between the body and the empyema that follows the second stage operation, and the mediastinum would be still more rigid and undoubtedly sufficiently so to make it perfectly safe to leave the thoracic wall wound wide open after the second stage. This would be of advantage in controlling infection as the gangrenous lobe could be packed off with acriflavine gauze every 24 hours, or even every 12 hours, whereas this is not done for 2 or 3 days if the incision is temporarily closed. I believe that such an interval between stages would be feasible if at the time of the first stage the diseased lobe were completely

surrounded by rubber dam (Linenthal 18) in which there were several small dependent holes for escape of fluid, in order to prevent its adhesion to the parietes. I shall use this modification for my next lobectomy patient. Additional advantages of this will be considered in the next section.

Second stage. Pre-operative postural drainage and medication and the position of the patient on the operating table are the same as have been described for the first stage. Slightly positive pressure nitrous oxide oxygen anesthesia is used so as to keep the newly adherent undiseased lobe from retracting from the thoracic wall. If there had been a three or four week interval between stages positive pressure would be unnecessary.

With the fingers the incision is reopened and the diseased lobe is completely freed from its adhesions. The oblique main interlobar fissure must first be identified beneath the pleural exudate so as to avoid freeing any of the undiseased lobe. It should be remembered that the normal sized lower lobe is of great height, extending from the fourth to the tenth or eleventh ribs in the para-vertebral line (Fig. 4).

A liver needle threaded with 80 centimeters of very heavy braided silk of great tensile strength and which has been boiled only once is held in the fingers, rather than in a needle holder, for greater delicacy of touch and is passed without force through the hilum of the diseased lobe close to the pericardium. Here the hilum is about 3.5 centimeters broad and the needle passes through it at approximately the junction of its upper quarter and lower three-quarters. The needle should not and probably does not pass among the great vessels and bronchus but above them, through the lower part of the web of parenchyma that lies between the lobes.

After the needle has been passed, the silk is divided at its middle and one half is then tied with a surgeon's knot as tightly as possible around the upper part of the hilum and the other half around the lower part. Each pair of ligatures is then made to encircle the whole hilum and is tied tightly.

The method of hilar ligation just described is the one that I have used until now. When, in my earlier cases, the ends of the tied ligatures were passed through the latissimus dorsi muscle in order to exteriorize the lobe, it was important that a transfusion ligature be used to prevent slipping. But as I no longer exteriorize the lobe nor resect it immediately after ligation, this is not necessary. Two or three superimposed simple encircling ligatures of heavy braided silk with surgeon's knots (Fig. 2) should be as effective as a transfusion ligature and be without the potential danger of the

latter. Encircling ligatures placed close to the pericardium of a fresh cadaver did not tend to slip distally. I shall use them for my next patient.

On several occasions I found that these tight ligatures of the indurated hilum did not completely shut off the blood supply to the lobes which remained partially viable and later needed to be removed with the actual cautery, in one or more stages, between which in one patient, there was a small hemorrhage from the stump. I have heard of one and possibly two sudden deaths that were apparently due to reaction of the lobe with an electric cutting current.

On two or three occasions I found that the ligatures occluded the pulmonary vein but not the artery and wet rather than dry gangrene resulted with great exudation of blood into the lobe and leakage of much bloody serum from it, requiring blood transfusion. In these patients the artery was closed by ligating the hilum, the lobe still being in place, with a live rubber tube (Lenhardt). It may be necessary to retie this tube more tightly each day for several days. In the future I shall apply this elastic ligature during the second stage operation, immediately after ligating with silk. I doubt if the elastic ligature alone could be counted upon immediately to occlude both artery and vein, unless the hilum were first tightly tied with silk.

In none of my patients has there been any known reflex cardiac or respiratory disturbance from tight ligation of the hilum close to the pericardium and in only the first 1 or 2 cases did I first inject procaine around the hilum. I have crushed the hilum before ligating in only one case and there was no ill effect, but since then I have felt that the risk of causing a fatal reflex or of fracturing a part of the hilum was greater than the obvious advantage of crushing the infiltrated hilum so that the ligatures would more surely occlude the vessels and bronchus. Morrison found in experimenting upon rabbits that crushing and ligating the hilum of one lobe caused no important reflex disturbance but that crushing the whole hilum of a lung caused almost immediate death unless the vagus nerve had been divided or blocked. He states that other experimenters found that this reflex did not occur if the whole hilum had been only ligated and not crushed.

I feel very strongly that it is better not to cut away the lobe after ligating its hilum but to leave it until it spontaneously separates at the line of demarcation at the ligatures, from 10 to 20 days after operation, or at least not to cut it away until a week or 10 days after operation. It is, of course, unpleasant to have a pulpy gangrenous lobe attached to the body for days but there are two very

real dangers of removing the lobe during the first postoperative week. If the hilar ligatures have not completely closed the vessels and bronchus these will leak blood, bronchial secretions, and air into the pleural cavity and the leakage of air might cause a fatal tension pneumothorax if the thoracic wall incision were closed and if the drainage tube should have become plugged. Even if the hilar ligatures completely occluded the vessels and bronchus at the time of removal of the lobe, there is a tendency for the ligatures to loosen because of pressure necrosis of the ligated tissues and because of the infection that is present in the hilar stump. A fatal secondary hæmorrhage or embolus to the brain or tension pneumothorax might be the result. Garré and many others who amputate the lobe ligate separately any vessels they find on the cut surface of the stump to help to avoid the danger of secondary hæmorrhage. It seems likely that there is a better chance of the thrombi that form in the vessels becoming solidly organized if the blood vessels are not cut across and their open lumens directly exposed within a week of the hilar ligation. The ligatures around the blood vessels are not a permanent barrier of protection to the thrombi central to the ligatures against the infection in the thrombi distal to the ligatures. Infection of the thrombi central to the ligatures would of course expose the patient to the dangers of secondary hæmorrhage embolism and bacteriæmia.

It seems reasonable to assume that primary resection of the lobe, with the considerable manipulation of the stump that the ligations and layered suture entail, exposes the patient to greater danger of embolism and brain abscess than if the hilum were merely ligated. Two of 46 patients operated on by several surgeons according to the Shenstone technique died from brain abscess.

Whittemore (36, 37) in a one stage operation deeply sutures the lung, as near to the hilum as possible to the extracostal muscles (and occasionally also ligates the hilum with a catheter) thereby steadying the mediastinum and as the lobe is not removed during the operation allowing infection to set in gradually. He has had 3 deaths among 10 patients. The fundamental principles of the Whittemore operation appeared to me as sound but my early actual experience with it dissatisfied me and I lost one of the two patients for whom I used it. My chief objections to it are these: (1) Infection of the entire pleural cavity is almost inevitable within a week of operation, by which time the sutures uniting the lung and extracostal muscles will have loosened, allowing the infected lung to slip into the pleural cavity which has not been

adequately prepared for so severe an infection. And as the undissected lobe has scarcely had time to become firmly adherent to the thoracic wall, or the mediastinum to become fairly rigid, the open pneumothorax, that occurs when the lung retracts from the thoracic wall may prove fatal in itself or through a pneumonia which such a pneumothorax favors. (2) Even the partial exteriorization of a lobe without the addition of a quite extensive thoracoplasty to cause the thoracic wall to drop well inward, produces traction upon the heart and great vessels of the mediastinum (Bolgiano Patek and Sailer, Sauerbruch and Robinson). It is difficult for the surgeon to predict whether or not the traction that he exerts upon the mediastinum in fixing the lobe in a more or less exteriorized position will cause dangerous disturbances of the cardiocirculatory system. In 2 of my patients I felt within 48 hours of operation that the traction was too great and so cut the sutures that were holding the partially exteriorized lobe to the thoracic wall.

In most of my two stage lobectomies I have exteriorized the lobe at the second operation. However, during recent months I have felt that in view of preparation of the pleura for infection and against "mediastinal flutter" at the first stage that extenization of the lobe at the second stage was not only potentially dangerous but entirely unnecessary. Therefore, in my last two patients I left the diseased lobe after ligation of its hilum in the pleural cavity and closed the thoracic wall incision tightly leaving an air tight drainage tube in the position described under "first stage." My present technique, therefore has no relationship with the Whittemore technique.

The wound in my last two patients was closed airtight so as to protect them against any harmful respiratory mediastinal movement that might possibly have occurred during the first 2 or 3 days after operation if the incision had been left open, because the gauze stroking of the mediastinal pleura 12 days before might not have sufficiently stiffened it. A catheter, whose outer end was clamped, was introduced into the lower pleural cavity alongside of the lobe for intermittent installations of Dakin's solution. Two or 3 days after operation which was 2 or more days before the bronchus might be expected to open spontaneously, the incision was completely reopened, as had been intended, and the pleural space around the gangrenous lobe was loosely packed daily with acridlavine gauze until the lobe was removed about a week later. This procedure proved to be entirely satisfactory. Theoretically it would be preferable not to close the incision at all after the second

operation but to keep the lobe available for inspection at any time so as to detect at once signs of wet rather than dry gangrene, any bleeding from the crushed hilum where it was crushed by ligation and also to eliminate the possibility of a tension pneumothorax that might arise from a known or unknown opening of any part of the lung. With a closed incision, bleeding would be detected and a tension pneumothorax prevented if the air-tight drainage tube were open but, if the tube had become plugged the diagnosis might be made too late. I believe that it will prove perfectly safe to leave the incision wide open after the second operation is completed if 3 weeks are allowed to elapse between the first and second stages so as to give the mediastinum plenty of time to become quite rigid. This interval of time should be possible if the lower lobe is surrounded by rubber dam at the first stage operation. The advantages of a 3 week interval between stages and of leaving the wound open after the second stage so as better to control infection were discussed in the last paragraph of the section, "post operative management (first stage)".

The patient is made to cough and expectorate before the Trendelenburg position of the operating table is changed.

The majority of the second stage operations have been performed in 35 minutes or less, from beginning to end. In most of the patients the systolic blood pressure was higher at the end of the operation than at the beginning; in the rest the drop was 10 millimeters or less, except that in one patient it dropped from 126 to 112. The pulse rose during the operation from an average of 124 to 130. The greatest increases were from 112 to 168 which 2 hours later was 136 and from 135 to 164, which 5 hours later was 120. There was usually an increase during operation of 10 or 20 and occasionally even more in the respiratory rate which decreased slowly during the following days.

Postoperative management (second stage). Opiates and carbon-dioxide inhalations are given as after the first stage and regular postural drainages are used for at least several days until normal expectoration can be counted upon to clear the lungs of secretion and thereby reduce the chance of pneumonia. For a day or so the sputum may be somewhat bloody due to trauma to the bronchial mucosa by the hilar ligatures. Instillations of 60 cubic centimeters of Dakin's solution through the catheter are begun immediately after operation and continued every 2 hours until the incision is reopened 2 or 3 days later when acriflavine gauze, in which several Dakin's tubes are held, is snugly packed around the gangrenous lobe and re-

newed every 12 or 24 hours. Acriflavine solution is instilled into the Dakin's tubes rather than Dakin's solution which might be harmful to the bronchus after it opens from 4 to 7 days after operation.

If the lobe is seen to be very dark and swollen an additional ligature of silk or rubber tube, or preferably both should be placed around the hilum so as completely to close the lobar or bronchial artery. A dry gangrenous lobe is small, shrivelled, and not tense. The lobe may be left until it falls away spontaneously in from 10 to 20 days, perhaps even then requiring cutting of the tough bronchus, or the gangrenous lobe may be cut off with scissors several centimeters distal to the hilar ligatures in not less than a week after operation.

After all of the gangrenous stump has been discharged, the granulating wound should be inspected to see if any of the ligatures remain attached and, if so gently removed. The originally air tight drainage tube should be gradually withdrawn.

Until the pleural hole and bronchial opening or openings are completely closed, the hole should be well packed with gauze. This not only prevents pocketing off of pleural abscesses but, very importantly, occludes the open bronchi, thereby enabling the patient to expectorate effectively.

The great hole that was occupied by the lobe decreases in size with surprising rapidity owing to compensatory emphysema of the remaining lobe to the progressive rise of the paralyzed diaphragm and to a slight extent to shifting of the mediastinum (Fig. 6). After 2, 3 or 4 months only a saucer-like depression, with one two or three bronchial openings, remains (Fig. 3). As soon as the sputum becomes scanty and no longer purulent, the mouths of the bronchi should be touched with 40 per cent silver nitrate solution every 7 or 10 days. This alone may cause complete closure of the bronchi and epithelialization then soon becomes complete. If however the bronchi resist closure by this treatment and if 3 or more months after operation, the sputum has disappeared and only a little clear mucus is being discharged from the bronchi, the bronchi and the wound can almost always be closed by a plastic operation (Fig. 4). Either a pedicled skin flap or a large latissimus dorsi graft, which is left attached at the antero-inferior rim of the thoracic wall defect, is turned over onto the open bronchi and covered by suturing together the edges of the original cutaneous incision after excision of scar tissue. Pressure is applied by the use of a snug dressing over a rubber bath sponge.

Purulent sputum is likely to persist for several weeks after the second stage operation. Until the hilar bronchus opens several days after operation much of this sputum may come from the diseased lobe itself because its stiff walled bronchus in an infiltrated hilum may have resisted complete occlusion by the hilar ligatures. After this period, some purulent or mucopurulent sputum may persist for several weeks. It probably comes in part from inflammation of the bronchi and trachea that was a complicating part of the bronchiectatic disease and in part from irritation of the exposed bronchial mucosa by the gauze packing. After removal of the diseased bronchi, the bronchial and tracheal mucosa gradually becomes healthy and sputum disappears.

The temperature and pulse are likely to be high for approximately 1 week after the second stage operation, the temperature usually being between 101 and 103 degrees and the pulse between 130 and 150, after which they gradually decline to normal though the pulse may remain somewhat elevated for weeks. Sometimes the temperature may become almost normal within 2 or 4 days, and sometimes there may be considerable fever for several weeks.

Owing to the severe reaction of most of the patients to the second stage and to the high fever and debilitating effects of both the disease and the operations, one or more blood transfusions have usually been given after the second operation and occasionally before either operation. Heliotherapy has sometimes been used during convalescence and exercises given to help to prevent scoliosis. This has occurred to an important degree in only 2 patients, in 1 of whom it is severe, but this patient is comfortable and goes to school and does farm chores, the other does heavy labor with a circus.

The postoperative defect in the thoracic wall where portions of three ribs have been removed is a relatively small one and cannot fairly be called a "deformity" (Fig 4). Bronchoscopy or a bronchogram (Fig 5) shows the remains of the lower lobe bronchus to be a short cul-de-sac, or a two-horned cul-de-sac if the lobe were resected just distal to the first lobar bronchial division. Good drainage toward the trachea, ciliary action, and the hehic hlast probably combine to keep this short stump free of bronchial secretions.

The technique that has been described has been evolved slowly from animal experiments that were begun 11 years ago and from experience with total lobectomy in man which began more than 4 years ago. Many staged cautery lobectomy has already been considered. My first experience with an fatal attack upon the hilum was in a patient whose

upper lobe was not adherent and for whom I performed the one stage exteriorization described by Whittemore (36). This patient died 8½ hours after operation with the appearance of a shock, part of which I now feel was due to undue traction upon the mediastinal structures by way of the exteriorized lobe. The same technique was used for the next patient. The lobe became only partly gangrenous and the viable remains were destroyed by the actual cautery in several stages. The patient is absolutely well. The next 5 patients were operated on according to suggestions that had been made by Samuel Robinson (23). In 1 of these patients the parietal pleura was merely exposed and the wound closed at the first stage; in 3 a gauze pack was placed on the parietal pleura before the wound was closed and in 1 the pleural cavity was opened and gauze placed around the diseased lobe until the second operation was performed 3 days later. The interval between stages in the other patients was 9, 5, 3, and 3 days, respectively. In all 5 patients the lobe was exteriorized at the second stage. In all of these patients, the pleural reaction was relatively unsatisfactory and the undiseased lobe was usually only loosely adherent to the parietal pleura.

The next main phase in the development of the operation was the gentle stroking of the pleura and elongation of the interval between stages to from 9 to 12 days. This has proved very satisfactory and there has been no death among the 6 patients operated upon (between April 1930, and April, 1932) according to this procedure. I shall use in the future such minor modifications of it as have already been considered.

Several other lobectomies have been performed during the period of evolution of the operation just considered but as they illustrate no difference in principle, but only minor modifications to suit particular cases, I shall not discuss them, except to mention the results.

RESULTS

I have personally performed (between January, 1928, and April, 1932) 18 total lobectomies, 3 of the patients (16.66 per cent) have died. Only 12 (each with a non adherent undiseased lobe) of these 18 have been operated upon according to principles that have been considered in the body of this article and 2 (16.66 per cent) of these have died (Table I). Six of these 12 have received the benefits of the developed technique and none of them has died.

All of the 12 patients suffered from clinically severe basal bronchiectasis and details of their cases are given in Table I. Four of them are cured

TABLE I.—TOTAL LOBECTOMY IN TWO STAGES FOR LOWER LOBE BRONCHIECTASIS

In all cases undissolved kyle was not adherent before operation

TABLE I.—TOTAL LOBECTOMY IN TWO STAGES FOR LOWER LOBE BRONCHIECTASIS (Continued)

In all cases undiseased lobe was not adherent before operation

After lobectomy										
Num- ber	Cough colds nose- acrid	Dyspnea	Complications	Preoperative results		No. of days in hospital	Gains in wt. (lbs.)	Present condition	Remarks	
				Open	Closed and wound closed Months after operation					
										How closed
1	—	—	Considerable asthma	—	3 1/2	Silver suture, L. muscle primary	20	20	Cured. Doing heavy labor with ease	Lobectomy 4:30 and 4:11:30
2	—	—	Chronic bronchitis and perforated pericardium	++	—	—	5	—	Died 14 days after second stage	Average postoperative course and temperature practically normal with to cold day. Then sudden epidemic of influenza. Patient died of terminal bronchopneumonia.
3	Cold	Slight	—	++	—	Therapeutic grafts	11	2	Improved. Household work	Present condition practically from direct tract dual to lobe removed. No pneumonia. Works 1 hour a day at home and farm work
4	Cough	—	0	—	20	Silver suture	12	10 1/2	Classically cured (but see Remarks). Regularly at school	There remains a dry bronchectasis of the upper lobe on basal lobectomy side
5	—	—	Pneumonia, pyrexia, and severe asthma	—	1	Muscle primary	10	37	Cured. At school and works in office or does chore on farm after ward	Waiting brace for scoliosis
6	—	—	Dyspnea and prob- ably moderate asthma	++	—	—	13 1/2	—	Died 48 hours after operation and partially ac- cidental attempt to free lobe from firm adhesions	Only moderate drop of blood pressure and rim of pulse remains. Dyspnea and difficulty in raising sputum were prominent
7	Moderate cough	0	Pulmonary tuberculosis	Occasion- ally open chest discharge	—	Silver suture, L. muscle closed	17	11	Greatly improved	Five months after lobectomy a few early tubercles seen in non-granular, and tubercle bacilli found at only one point. Patient greatly better after operation except up head of a small gold safety pin
8	Slight cough	0	—	+	14	Spontaneously	10	31	Greatly improved	Tuple pyrexia disappeared after lobectomy. Quiescent bronchectasis in contralateral lobe. Bronchial sputum cleared. Patient greatly better after operation, with moderate loss of weight
9	Occasional cough	0	—	—	1 1/2	Spontaneously	14 1/2	3 1/2	Greatly improved. Par- tially at school	There remains a practically dry bronchectasis of the upper lobe on basal lobectomy side
10	0	0	Chronic otitis media, nas- titis, and paranasal sinusitis	—	1 1/2	Silver suture	19	6 1/2	Greatly improved	Chronic infection in ears, sinuses and paranasal sinuses as does a practically dry bronchectasis of the upper lobe on basal lobectomy side
11	0	0	Acute bronch- itis	—	4 1/2	Silver suture	14 1/2	3 1/2	Cured	All symptoms of peritonitis, including abnormal findings in peritoneal fluid, disappeared about five months after lobectomy
12	—	—	Upper thoracic emphysema, tracheal stenosis, pyrexia	—	—	—	19	—	Operation too recent for re-evaluation as to re- sults. Good prospect for cure	Emphysema is now small. No signs of pyrexia

(see, however Case 4) 4 are greatly improved and approximate a condition of cure 1 is moderately improved none is unchanged or worse, 3 are dead. One has been operated upon too recently for the result to be judged. By excluding this patient, 9 (81.81 per cent) of the 11 whose results are known are either cured or improved 6 of the 9 have solidly healed wounds without a bronchial fistula and have little or no sputum. Consideration of the 2 deaths in retrospect leads me to believe that 1 of them (Case 2 Table I) was unavoidable and that the other (Case 6) was due to an unwise attempt to free a lobe from tough investing adhesions.

Six other lobectomy patients were operated upon by me (excluding 2 patients, 1 with carcinoma, the other with progressive multiple and already drained abscesses, operated upon with fatal result by other members of my staff) by techniques that are not directly related to the technique that is the subject of this article. The Whittemore operation with the modification of tightly ligating the hilum close to the pericardium before exteriorizing the lobe was used for 3 with 1 operative death and 1 cure. The Everts Graham technique was used in many stages for a total lobectomy in 3 patients with dense pleural adhesions 1 is without symptoms and his bronchial fistulae have been closed with a muscle plasty and the other is slightly improved but has bronchiectasis of the upper lobe which is apparently uninfluenced by a very extensive thoracoplasty. One patient had a gigantic abscess and the other multiple abscesses almost the entire lobe being involved in each case. The abscesses had been drained in both patients before lobectomy which was performed by interpleural isolation of the lobe and ligation of the hilum. One is cured and the other has no sputum but has been operated upon too recently for closure of his bronchial fistulae.

Sixteen of the total 18 patients fulfilled the criteria that I believe necessary for safety in that they either had extensive adhesions over the undiseased lobe or they were caused to form before lobectomy was performed. Two (11.5 per cent) of these 16 died 1 of them after an unwise attempt to separate adhesions before the lobectomy stage itself was undertaken.

Few operations require for a successful result such meticulous attention to pre-operative, operative and postoperative details as does lobectomy.

OTHER METHODS

Almost every imaginable way of performing a lobectomy has been proposed or tried. The important methods have been described in a recent

article by Ballou, Singer and Graham, to which the reader is referred as well as to the original articles of the surgeons whose operations will now be considered. I shall limit myself here to a brief discussion of the principal types of operation.

The most fundamentally important difference of opinion exists today between those who favor one stage and those who favor two or more stage lobectomy. Many of the early lobectomies were performed in one stage. Lilienthal, a pioneer in lobectomy reported in 1915 the largest series of one lobe lobectomies in one stage there were 10 deaths (58.8 per cent) in 17 patients. There were 3 deaths in 5 two stage one lobe lobectomies and at that time Lilienthal preferred the one stage operation but used a two stage operation if the patient's condition was too poor to withstand completion of the operation in one stage. In a personal communication of May 6 1932 to Ballou, Singer and Graham, reporting what is presumably his entire experience with lobectomy for bronchiectasis (43 cases with 17 deaths) (64.3 per cent), Lilienthal announces his preference for a two stage procedure in which he rubs the pleura with gauze dipped in tincture of iodine and, at the second stage, resects the lobe, anchors the ligatures to the thoracic wall, separately ligates the vessels, and closes the chest except for a water seal drain. Sauerbruch (31) in 1927, stated that he had had 6 deaths in 6 one stage lobectomies.

The high mortality figures of one stage operations and also of the two or more stage operations of only a very few years ago resulted in great pessimism about the propriety of employing lobectomy at all and this pessimism is evident in most of the present medical and surgical textbooks. In 1927 however Whittemore reported 5 cases with only 1 death, operated upon by a one stage exteriorization technique that justly aroused interest and hope. This operation has been discussed elsewhere in this article. Brunn, in 1929, reported 6 cases with 1 death, operated upon by a one stage technique that was modeled after that of Lilienthal and of Garré. Shenstone and Jones, operating in one stage, used an instrument with a cord snare that firmly squeezed the hilum without devitalizing it, while the lobe was being amputated and the stump closed carefully in layers, the last layer effecting pleura to-pleura apposition and finally the stump was sutured to the under surface of the upper lobe. These features of the operation caused healing of the stump without bronchial fistula in the majority of cases. With this technique Shenstone and Jones lost only 2 of their first 13 patients and Archibald and Bethune 1 of their first 6.

Judged by the critical standard of mortality percentage the figures given in the preceding paragraphs renewed hope in lobectomy as a reasonably safe operation but the latest available reports of these surgeons are far less encouraging. Whittemore (37) has lost 3 of 10 patients. Brunn (10) 2 of 8. Shenstone and Jones (34) 5 of 16. Archibald (4) and Bethune 2 of 9 and 3 other thoracic surgeons who I have heard have used the Shenstone technique¹ have lost 2 of 3 patients. The combined figures of these cases, exclusive of the last 3, are 12 deaths (27.9 per cent) in 43 patients.

None of Shenstone's and Jones' patients died from hemorrhage from the hilar stump, tension pneumothorax, pleural or mediastinal infection, one or the other of which has been responsible for 2 deaths following the Shenstone operation in another clinic and for many deaths after operations performed according to other one stage techniques.

There can be no question but that a one stage lobectomy through an intercostal incision with first intention union of the incision and of the lobar stump and with only a temporary air tight intrathoracic drainage tube has obviously great advantages over any other technique that has been conceived and is a surgical ideal. But if in theory and practice a one stage lobectomy is considerably less safe for the patient than a two stage lobectomy the ideal must be sacrificed. The best of the one stage figures to date are distinctly inferior to the best of the two or more stage figures.

Theoretically any one stage operation especially in the presence of a non-adherent undiseased lobe seems to me as dangerous as the figures indicate. A one stage operation takes much longer to perform than a two stage operation and for various valid reasons the time factor in a major operation within a wide open pleural cavity upon patients so ill with grave suppurative pulmonary disease as to require a lobectomy probably has considerable bearing upon the occurrence of postoperative pneumonia which has been a prominent cause of death in the one stage reports. I am told that the Shenstone operation takes about 1½ hours though it has been performed in 45 minutes. It appears to me that in the long run pneumonia will not be combated more effectively by occluding the stem bronchus on the diseased side with various balloon devices than by the simpler measures that have been considered in this article.

One of the greatest theoretical as well as actual dangers of any one stage operation is that of infection of the pleura, mediastinum, blood, and thoracic wall. The intrabronchial secretions of

these bronchiectatic lungs are loaded with highly virulent aerobic and anaerobic organisms. When the lobe is resected some contamination of the pleura in the neighborhood of the hilum from the opened bronchus is almost inevitable. In spite of careful protective packing. Although obliteration of the entire open pleural cavity which Shenstone's technique tends to accomplish shortly after operation, does much to prevent the development of infection it does occur not rarely. A virulent infection of an unprepared virgin pleura is certainly a grave complication as is progressive infection within the already infected hilar stump which has been closed by suture in layers. This infection may not only quickly reach the mediastinal areolar tissue (Archibald, 4) but it may break down the catgut sutures that were used to close the bronchus and pulmonary vessels and break down the new thrombi with resulting secondary hemorrhage (Archibald, 4) and bacteremia (Archibald, 4). Opening of the bronchus may cause fatal tension pneumothorax if the pleural drainage tube has become occluded by blood (Brunn, 8) or expanded upper lobe. If a patient is given large doses of opiates to help to keep him from coughing open the sutured bronchus the danger of stasis pneumonia is greatly increased.

If the thoracic wall incision becomes infected and breaks open before the mediastinum has had time to become stiffened or the upper lobe to become firmly adherent to the costal pleura the patient is exposed to grave danger of death from mediastinal flutter or its complicating pneumonia. Lillenthal (18) has warned against the danger of anaerobic infection of the thoracic wall incision (whose tissue spaces have not been sealed by a preliminary operation). A further danger of the Shenstone operation is that the temporary snare around the lobar stump may slip before the great pulmonary vessels have been closed by suture, this occurred in one of Archibald's (3) cases but the hemorrhage was controlled before a dangerous amount of blood had been lost. The increased liability to brain abscess after primary lobar resection has already been discussed.

The evidence that is now available seems to me to dictate the conclusion that the margin of safety is far narrower with a one stage than a two stage operation. Consideration of one stage lobectomy should not be concluded without mention of the delicate and successful technique that Churchill (12) used in removing a carcinoma of the stem bronchus together with two pulmonary lobes and which will shortly be described by him. Churchill (11) prefers a two stage operation preceded by temporary phrenic nerve interruption, for con-

¹Todor Edwards, in recent letter advises us that he has lost only 2 of 10 patients operated on by the Shenstone technique.

malignant pulmonary suppuration if the pleura are non-adherent. He has performed six lobectomies for bronchiectasis without a death, surely a remarkable record. One of his three lobectomy patients for carcinoma is well and two died.

To Samuel Robinson (23-24) should go the honor of being the first to see clearly the important advantages of obtaining adhesions of the undiseased lobe before undertaking the lobectomy itself. It was because his various methods of producing these adhesions just missed being sufficiently effective that lobectomy was not accepted as a useful operation 15 years ago. In his last clinical report he (26) stated that, if it were only possible to get the undiseased lobe anchored and to remain anchored the chief obstacle to successful lobectomy would be removed.

Sauerbruch has apparently been frequently dissatisfied with the techniques he has used and has often changed them. At first (28) he used a one stage operation then (28) a "piece by piece" (stückweise) lobectomy then (28) ligation of the lobar artery and removal of the lobe at a second stage then in 1928 (32) presumably in stages, phrenicectomy, thoracoplasty, ligation of the lobar artery, and if it were possible to free the lobe to the hilum, resection and separate ligation of the artery and vein when feasible but mass ligation when the hilum was especially tough. In weak patients and apparently for others, he advised instead of this procedure removal of a few ribs and an extrapleural pneumolysis with paraffin filling and 6 to 8 weeks later an extensive thoracoplasty with the paraffin in place and 3 to 4 weeks later, removal of the paraffin and of the lobe as the final stage. He also wrote at this same time (1928) of having used an extensive thoracoplasty and later after separating the lobe from adhesions, packing gauze around it and repeating the packing and pressure and, finally tearing the lobe free from its adhesions and ligating its hilum with a rubber tube (Zaaijer 38-39). Nissen, in 1929, writing from the Sauerbruch Clinic, advised using an elastic hilar ligature (Lenhartz) if the hilum were not well fixed in dense scar and if it were, he advised resecting between mass ligatures. Nissen, in 1930 described in some detail the use of paraffin either extrapleurally or intrapleurally when some pleural adhesions already exist, in an effort to produce pleural adhesions as well as to compress the diseased lobe. He advised 2 week intervals between the first and the second and the second and third stages instead of the much longer intervals that Sauerbruch had recommended 2 years before. Nissen at that time proposed surrounding a non-adherent diseased lobe with a cloth bag (Robi-

son in 1917 surrounded it with a gauze pack). The last report from the Sauerbruch Clinic came from Nissen in 1931 emphasizing the importance of having adhesions all the way to the hilum and advising repeated packing before removal of the lobe with an elastic ligature but it is difficult to tell from this article whether or not Sauerbruch has as yet entirely lost his faith in the ability of extrapleural paraffin to form sufficiently extensive pleural adhesions to make lobectomy safe. Denk, in 1929 observed that extrapleural paraffin placed over the diseased lobe as Sauerbruch places it does not cause formation of adequate adhesions over the undiseased lobe, and I do not understand how it could be expected to cause the desired reaction in the mediastinal and hilar pleura.

It appears to me that the Sauerbruch techniques are unnecessarily complicated, that what seem to me as unnecessary major operations (stages) increase the patients' jeopardy and that in none of them is any direct effort made to create firm adhesions over the undiseased lobe. These same criticisms apply to the technique employed by Zaaijer and Coryllos. It is not made clear by Sauerbruch, whether or not he has included in his reported statistics any deaths that may have occurred during the thoracoplasty and other stages preliminary to the lobectomy stage proper. If I should not count the death that occurred in Case 6 of Table I after the operation that was performed 10 days before the intended lobectomy my mortality would be 1 death in 21 cases or only 4.7 per cent instead of the 16.6 per cent that I consider the correct figure for the series about which the article is primarily written. I recognize that in a narrow sense a statistical report on "lobectomy" might be considered to include only those patients upon whom lobectomy was actually accomplished, but on the other hand, any death occurring after any stage whatever that the surgeon considers to be a necessary preliminary to the lobectomy itself should properly be counted as a lobectomy death.

The following reports of two or more stage lobectomy (but usually without clear indication as to what techniques were used) have been made from the Sauerbruch Clinic (exclusive of the "piece-by-piece" lobectomies in which there were 2 deaths in 9 patients) 1920 6 lobectomies, 0 deaths 1924 10 lobectomies, 3 deaths 1927 (30) 23 lobectomies, 3 deaths and all the others were cured, not only improved" 1928, 26 lobectomies, 3 deaths 1929 (Krampf) 28 lobectomies, 3 deaths 1931 (Nissen) 38 lobectomies, 4 deaths. These are indeed phenomenal figures and especially startling is the apparent claim that there was 1 death

in 7 years among 28 patients (compare the 1924 and the 1931 figures just given). Also startling is Sauerbruch's bald 1927 statement that every one of the 20 patients who have survived the operation is actually cured by which should be understood a solidly healed wound without any bronchial fistula whatever and 5 grams or less sputum in 24 hours. When however, Sauerbruch's one stage and piece-by-piece lobectomy cases are added to his two or more stage lobectomy cases there is a total of 53 cases with 12 deaths a mortality rate of 22.6 per cent.

SUMMARY

1 The many dangers inherent in resection of an entire lobe of the lung are expressed in the prohibitive mortality rate of 53.4 per cent for 127 collected cases in which recent improvements in technique were not applied.

2 Another series of 115 cases has been collected from the 8 foreign and native clinics which have contributed most to the study of lobectomy with a mortality rate of 21.5 per cent.

3 In this article are reported 18 personal cases with 3 deaths a mortality rate of 16.6 per cent. None of the last 8 has died.

4 The undiseased lobes of 12 of these 18 patients were not adherent and special measures were taken to overcome this particular danger. Two died (16.6 per cent). Only 6 of these 12 patients have received the benefits of the developed technique and none of them has died.

5 The principles of the operation and its technical details are given.

6 The other modern lobectomy operations are critically considered.

INTRAVENOUS PYELOGRAPHY

DR. MED. OTTO DYES WUNDERBURG, GERMANY

Director of the Radiological Institute of the University Surgical Clinic, Würzburg

ONLY a short time has elapsed since the fundamental researches of Roseno von Lichtenberg, Swick, Binz, Lichtwitz, and Hecht first made it possible to obtain adequate radiographic demonstration of the urinary tract by means of an intravenously injected contrast agent. Nevertheless, a large number of important papers have already been published which have led to the rapid development and exploitation of this valuable diagnostic method. Haensch recently gave a comprehensive review of the scope and application of the method at the International Radiological Congress in Paris, and at the same time summarized the history of its discovery. Anyone wishing to obtain a clear outline of the development of the method from unsatisfactory beginnings into a valuable addition to our diagnostic armamentarium should not fail to consult Haensch's article.

It is unnecessary to recapitulate here the steps in the development of the method, since Haensch has traced this in its entirety up to and including the introduction of the newest contrast medium for intravenous pyelography, uroselectan B, though the element of time has prevented him from reporting upon any very extensive experiences. In contradistinction to Haensch, we incline to the opinion that to a certain extent uroselectan B represents a final stage in the development of intravenous pyelography. Not only has the reduction of the amount of solvent to 20 cubic centimeters greatly simplified the application of the method but in addition the excretion of iodine in the urine has attained a perfectly adequate concentration for contrast purposes and further under ordinary circumstances, it is limited to a short period of time.

Uroselectan B is a pyridin derivative with 51.5 per cent of organically combined iodine. Twenty cubic centimeters contain 15 grams of the substance dissolved in a 10 per cent solution of invert sugar. This amount is sufficient to give clear pictures not only of the urinary tract but also of the renal parenchyma. Although the solution is hypertonic, the addition of invert sugar has, according to our experience, prevented the appearance of such symptoms as a sensation of warmth, thirst, perspiration, nausea or vomiting; we have not observed such effects after the injection of uroselectan B. Occasionally the

patients complain of a drawing pain along the veins in the upper arm radiating into the forearm. These pains are a sign that the injection has been carried out too quickly, and can be avoided by injecting more slowly. They are not the precursors of thrombosis, a phenomenon which we have not observed in any case.

Since uroselectan B does not influence the coagulation time or sedimentation rate (von Lichtenberg), there need be no fear of the occurrence of thrombosis or embolism, provided the technique of injection is correct. According to Haensch, uroselectan B may be used in all conditions with the exception of uremia, and our experience confirms this view. Analysis of the urine (Heckenbach) shows that in the first hour following the injection (especially the first 10 to 30 minutes) uroselectan B is excreted almost quantitatively; there is a marked diuresis and the urine shows a high percentage of iodine (about 5 per cent). This property is responsible for the relatively good contrast of the films obtained and for the fact that the ureters are more often filled throughout their whole extent than is the case with other contrast agents. This observation is of particular importance as previously individual authors have considered the demonstration of the ureters in their whole extent as a sign of a pathological condition or irregular function. In spite of all its obvious advantages, we must entirely agree with Haensch's statement that intravenous pyelograms also are upon occasion useless. This is due to the fact that the pictures are relatively weaker in contrast than those obtained with retrograde pyelography. While practice gradually enables the eye to interpret the meaning of the pictures, it sometimes happens that the amount of gas or feces in the gut seriously interferes with the demonstration. Many methods are adopted to avoid this and we have gained the impression that, in ambulant and unprepared patients, this phenomenon is least frequently and less markedly observed. Nevertheless, it is not possible to exclude such an occurrence with absolute certainty and under such circumstances the demonstration of the renal pelvis by means of retrograde pyelography will give better results.

Furthermore retrograde pyelography remains valid not alone for such cases. Flaumer has recently pointed out that the basis of intravenous

pyelography and therefore its indications are entirely different from those of retrograde pyelography. With the latter method we are dealing exclusively with the demonstration of a normal or pathological condition of the lumen of the urinary tract. In this connection, it must not be forgotten that if the contrast agent is instilled at a pressure higher than the normal for the urinary tract, an artificial and deceptive dilatation may take place and an accurate picture of the size of the renal pelvis is not necessarily obtained. The intravenous method while it demonstrates gross changes in the anatomical condition also gives us information as to the size and shape of the renal parenchyma and of its functional activity. This fact enhances the value of the intravenous method from the point of view of diagnosis. From the technical standpoint the intravenous injection of 20 cubic centimeters of uroselectan B is far more agreeable for the patient than ureteric catheterization. It follows, therefore, that the intravenous method with its superior adaptation to physiological conditions, should in most cases precede the application of the retrograde method; the employment of the latter being only necessary when the information given by the former proves insufficient.

In accordance with the observations of Heckenbach on the rate of excretion of uroselectan B the X-ray exposures are best made within a period of 10 to 50 minutes after the injection. In some of our cases excellent pictures of the renal pelvis were obtained 6 minutes after the completion of the injection, this having been carried out with the patient lying on the X-ray table (Fig. 1). Occasionally, the most strongly contrasting pictures were obtained by taking a series of films at intervals of 10 minutes up to 90 minutes after the injection. Perlmann refers to the fact that previous investigation of the rate of excretion of indigocarmine may give some indication of the best time for making the exposure. When the kidney function is damaged the excretion of the contrast agent may be delayed on one or both sides and the X-ray investigation may have to be prolonged even into the next day, the exposures being made at longer intervals, before a complete picture is obtained. The pictures gain in definition when the contrast agent is held up in the renal pelvis by means of compression. We were not able to convince ourselves that pressure over the bladder region was of much importance for the success of the pyelogram. It is far more effective to constrict the ureters at the level of the sacrum (Ziegler Koehler etc.) in any case pressure should not be applied until urine containing the

Fig. 1. Taken immediately after injection. Position of right kidney low normal pelvis. On the left renal pelvis is double and two small kidney shadows are seen which in combination give rise to a renal contour somewhat similar to the normal.

contrast agent has collected in the renal pelvis. If the compressor is applied too soon urine containing the contrast agent will become mixed with urine free from it and the contrast in the X-ray plate will suffer. With the use of compression the middle section of the ureter remains unfilled and is not therefore demonstrable. This condition must not be confused with occlusion of the ureter due to stone etc. Further if the renal pelvis appears large, there is no reliable method of knowing whether this is due to the stasis produced by the compression or not. For this reason we loosen the compressor as soon as a sufficiently good picture of the renal pelvis for diagnosis has been obtained. In spite of all precautions however it is not always possible to demonstrate the urinary passages in their entirety. Slight changes in the contours of the renal pelvis in particular (small shadowless stones, small tumors tuberculosis etc.) are sometimes better demonstrated by ascending (retrograde) pyelography.

In view of the complexity of the subject and in order to be as concise as possible we would once again refer the reader to Haenisch's paper for a description of various individual points and of the normal appearances. We will confine ourselves here to the discussion of various important points as they arise in the course of describing some especially typical cases.

Figure 1 was obtained immediately after the injection. The left renal pelvis is double. The pelvis can be well seen even to the finest details of the

Fig. 2. Forty-five minutes after the injection. Con-
centric enlargement of the right renal pelvis which has a
prolongation, similar to the root of a radish, opening into
the ureter. The left kidney shows no excretion and no
shadow of the parenchyma. The bladder is empty.
Diagnosis: left kidney not functioning on account of
dilatation of the parenchyma from the hydronephrosis.
Intermittent hydronephrosis of right kidney (see text)

calyces. In the lateral renal pelvis practically
only the calyces are filled and the anatomical pel-
vis shows only a thin contrast shadow. Such
pictures often alternate with others in which the
same renal pelvis is completely filled and clearly
demonstrable. The phenomenon is especially
noticeable in small sized renal pelvises, and we
attribute it to transient contractions (Mangen,
Haensch). In this case, however another
possibility must be considered. The parenchyma
corresponding to both renal pelvises is markedly

penetrated by the contrast solution and is, there-
fore, clearly visible. The parenchyma shows the
appearance of a double kidney and both parts are
nearly reniform. The lateral portion of the
parenchyma is the smaller in relation to the size
of the pelvis. The larger portion of the double
kidney to which the medially placed pelvis be-
longs, lies with its most voluminous part corre-
sponding at every point exactly with the position
of the anatomical renal pelvis in the lateral section
of the kidney. These topographical relationships
suggest that possibly the laterally placed renal
pelvis is developed only as a narrow fissure and
that as a result the thin layer of contrast urine
lying in it is not sufficient to demonstrate the
pelvis. This possibility must be the more seriously
considered since in subsequent exposures no im-
provement was seen in the demonstration of the
renal pelvis. The appearance is not therefore due
to transitory contractions but to a permanent
condition. Still more the excretion of the con-
trast urine on this side was practically complete at
the end of 30 minutes after the injection. In the
pyelogram obtained at this time, "the renal
parenchyma showed the normal degree of opacity
to X rays, from which it may also be assumed that
the excretion of contrast urine on this side has
come to an end. For the same reason it is no
longer possible in the last exposures to differen-
tiate between the two sections of parenchyma of
the double kidney.

To this must be added the fact that even 10
minutes after the completion of the injection the
parenchyma and pelvis of the left side show only
very weak shadows. On the other hand the
parenchyma of the right kidney was unusually
clearly visible during the whole time of observa-
tion up to the end of 30 minutes, that is to say it
was heavily filled with contrast agent. Here too
contrast urine was present in the pelvis immedi-
ately after the injection. The best degree of filling
was obtained 10 minutes after injection but also
after 30 minutes the renal pelvis was as easily
demonstrable as immediately after the injection.
Only after 30 minutes did the pictures gradually
become less dense. It cannot be said with
certainty whether or not these chronological
differences in excretion are due to the obvious
congenital malformation of the left kidney. Much
greater differences in the excretion time are
described by Haensch in such cases, however
pathological changes are undoubtedly present.
But in this case also it is particularly worthy of
notice that not so much the excretion but the
accumulation of the contrast agent in the paren-
chyma, first sets in on one side long after the

Fig 3. Thirty minutes after injection. Normal pyelogram on left side. On the right side moderate dilatation of the renal pelvis with flattened out calyces. The ureter is slightly dilated as far down as the sacral region. In its neighborhood traces of contrast agent used for the demonstration of an abscess fistula are to be seen. Diagnosis hydronephrosis due to involvement of the ureter in adhesions resulting from a retrocolic abscess due to an attack of appendicitis during pregnancy

Fig 4. Twenty minutes after injection. The right kidney is displaced upward and is somewhat compressed. The neck of the renal pelvis, which is normally directed downward, is turned inward and the ureter filled with contrast urine runs downward along the right border of the vertebral column. While the excretion of contrast urine has passed its maximum point on the left side, on the right side the intensity of the shadow remains the same. One can see "tufts" which are due to filling of the renal tubules with contrast urine, and which appear as continuations of the ends of the calyces. The renal parenchyma is completely intact. Diagnosis retroperitoneal lipoma.

maximum point of excretion has been reached on the other side. Sufficient observations have not as yet been made to enable one to say how far small chronological differences in the penetration of the contrast agent into the parenchyma and its excretion into the renal pelvis are physiological or otherwise. It cannot, therefore, be decided with certainty whether the above described functional condition is pathological. An important point, however is the fact that the accumulation of uroselectan B in the renal parenchyma can take place at different times in the two kidneys. Further it can be clearly shown that unilateral anuria due to prerenal causes does not lead to such a degree of compensatory activity in the other kidney as to permit the latter to excrete the whole of the contrast agent but rather should it be said that the first kidney can later make up for its deficient activity. For this reason the process of excretion must be observed if necessary over a prolonged period.

Figure 2 is a reproduction of one of the pictures obtained from a case in which such considerations

as mentioned were of clinical significance. The pelvis of the right kidney is greatly enlarged and presents flattened contours on all sides. The cusps of the calyces are also enlarged and flattened out. The renal pelvis runs downward sharply and irregularly like the end of a radish, which is strongly suggestive of a constriction of the ureter at this point. The exposure was made 45 minutes after the injection and is in the main similar to its predecessors. The accumulation of the contrast agent in the kidney parenchyma cannot be demonstrated since it is obscured by a collection of gas in the colon. None of the films showed the presence of contrast urine in the bladder. Only after hours of delay was the contrast fluid evacuated from the renal pelvis. This observation definitely shows the presence of an intermittent hydronephrosis. Since the ureters cannot

Fig. 3. 30 minutes after injection. Both renal pelvis are filled with contrast urine, the right being lower than the left. The right renal pelvis is much nearer the middle line than normal so that its two lower calyces which are almost vertical lie immediately above the lateral process of the fifth lumbar vertebra. Shadow of the renal parenchyma poor on both sides. Probable diagnosis, horseshoe kidney.

be demonstrated in all cases, this diagnosis can obviously be made only when contrast urine consistently fails to fill the bladder—that is to say when the other kidney excretes no urine into it as happened in the case under consideration. We were able to observe this case uninterruptedly for only 9 hours after the injection and 24 hours after the injection we made another control exposure with exactly the same result. At no time in the course of the examination was contrast urine found in the left kidney or ureter.

Such findings can be correctly interpreted only in association with the general history of the disease and the results of other examinations.

A farmer, aged 49 years, complained of attacks of pain in the left upper abdomen and loin for the last 12 years. These have increased in frequency and of late have been accompanied by vomiting and constipation. The corresponding area is tender on examination and palpation.

Intake and excretion of water maintained a balance during a period of a week. The specific gravity of the urine varied from 1018 to 1020. The test for albumin was positive. The sediment showed large numbers of erythrocytes and many leucocytes. No edema was present. The patient excreted 375 cubic centimeters of urine 1 hour after taking 1,000 cubic centimeters of tea and after 2 hours 425 cubic centimeters of a specific gravity of 1003. On a dry diet the specific gravity of a small quantity of urine passed in the evening varied from 1017 to 1020. Methylene blue was excreted from the right ureter 3 minutes after injection and from the left in 6 minutes. The urine from the left ureter was only very faintly tinged with blue. Retrograde pyelography was not successful on the left side. On the right side, a pyelogram similar to that shown in Figure 4 was obtained. A review of the individual findings permitted the diagnosis of functional deficiency of the left kidney together with maintenance or perhaps a compensatory increase of the functional activity of the right kidney. At operation the parenchyma of the left kidney was found to be almost completely destroyed. Behind the kidney which was closely adherent to the surrounding structures, was rigid walled renal pelvis. Its lumen was compressed to a small slit, from the lower lateral pole of which came the ureters. A few drops of cloudy urine could be expressed from it. Dilatation of the pelvic lumen was impossible on account of the rigidity of its walls.

Thus while retrograde pyelography could only show the anatomical changes of the right renal pelvis, intravenous pyelography showed that the kidney had preserved its functional activity. Absence of any contrast agent in the parenchyma of the left kidney justified the conclusion that the power of concentration of the left kidney for the given test substance (i.e. uroselectan B (Lichtwitz)) was as deficient as for indigo and other dissolved substances. It could also be assumed that the unilateral functional deficiency was responsible for the observed disturbances in the fluid exchange. In this connection it must not be forgotten that there is always the possibility of reversible suppression of function particularly in association with ureteric calculi.

In another case the establishment of the diagnosis was more simple (Fig. 3). In this patient a hydronephrosis had developed as a result of a retrocolic abscess following upon appendicitis during pregnancy, the right ureter having been involved in adhesions. In this case also the intense shadow produced by ascending (retrograde) pyelography is characteristic. Hydronephroses due to mechanical obstruction are excellent cases from the technical standpoint for intravenous (descending) pyelography since they cannot always be filled from below with the same degree of certainty. The question arises as to whether the increased contrast obtained is due to a greater concentration of iodine in the urine or to the fact that the X-rays have to pass through a thicker layer of contrast urine. This can be definitely decided only by estimating the iodine

content of a specimen of urine removed through the ureteric catheter from the intensity of the shadow of the ureters in our film however, it is evident that no appreciable increase in the iodine content of the urine has occurred and that the increased contrast obtained is due rather to the thickness of the hydronephrotic sac and the thickness of the layer of contrast urine contained in it. The ureter is especially dilated in its ilio-lumbar portion. At the point where it passes into the small pelvis the width of its lumen is normal. The seat of the constriction must therefore be searched for in the region of the sacro-iliac joint. This point was also indicated by investigation of the course of the abscess fistula with iodipin (Traces of the iodipin are to be seen as fine flecks of metallic density from the neighborhood of the ilium up to the renal pelvis and ureter). On the opposite side the excretion of uroselectan B is normal.

A characteristic case for intravenous pyelography may be briefly referred to here. In a 23 year old household worker a solid tumor with a smooth upper surface was found filling the whole of the right abdomen. It had gradually grown to its present size and had displaced the ascending colon forward and toward the middle line. As is shown in Figure 4 there was a similar displacement of the right ureter. Other clinical signs contributed nothing to a more definite diagnosis.

After intravenous pyelography had been done the possibility that the tumor was connected with the kidney could be definitely excluded. This opinion was justified not only by the fact that no characteristic changes were found in the renal pelvis but far more because the renal parenchyma was filled with the contrast agent and its contours were on all sides well defined and the mottling such as would have been present in the presence of a tumor was entirely absent. This fact was definitely demonstrable in all the films. Actually the condition was due to a retroperitoneal lipoma weighing 3 pounds. In this case also we observed a difference in the time of excretion of the contrast agent by the two kidneys. Figure 4 was taken 20 minutes after the injection. At this time the excretion of contrast urine on the left side was, as in Case 1 already on the decline. As a measure of this we must consider not only the filling of the renal pelvis with contrast urine but also the intensity of contrast of the parenchyma. In a series of films it is easy to recognize the increase and decrease of intensity which correspond to the functional activity of parenchyma and renal pelvis.

In well contrasting pyelograms such as the present, the urinary tubules are not infrequently

Fig. 5B. Taken in oblique position showing left kidney pelvis. The pelvis and the upper part of the ureter form a curve concave posteriorly. The upper sections are placed more posteriorly than the lower. Probable diagnosis, horseshoe kidney.

demonstrable and give rise to the appearance of 'tufts' which converge upon the ends of the calyces. These tufts are the same as those which as is well known are sometimes found after retrograde (ascending) pyelography. In comparison with the latter however the appearance obtained with intravenous pyelography is less distinct. Individual urinary tubules cannot be distinguished from their neighbors a fact which supports the theory that the urinary tubules can not be demonstrated by retrograde pyelography unless they are distended.

Intravenous pyelography was carried out in a 26 year old farmer who complained of trouble following a kick in the region of the right loin sustained during the previous year. Ureteric catheterization could be carried out only on one side on account of the displacement of the mouths of the ureters. Figures 5A and B which were obtained in this case show that in addition to this anomaly of the ureter the kidneys also had some peculiar features. The right kidney was more than one vertebra lower than normal and was partly displaced medially in front of the vertebral column. The left kidney lay obliquely. In order definitely to exclude the unlikely diagnosis of a floating and dropped kidney an exposure was made in the upright position (vide Röfo) which showed no alteration in the position of the kidney. It should be pointed out in this connection that the taking of pyelograms in the vertical position which is necessary in some cases has been greatly

simplified by intravenous pyelography. With the retrograde method the presence of a cystoscope and ureteric catheters makes this position very unpleasant for the patient unless special arrangements are made.

Unfortunately the parenchyma contained so little of the contrast agent that it was not possible to prove or exclude the presence of a horseshoe kidney which seemed the most likely diagnosis. On the other hand both renal pelves were so well filled with contrast urine that by the combined use of a tube and a lead screen it was possible to obtain oblique views of them one of which is reproduced in Figure 5B. The whole of the left renal pelvis can be clearly seen. The central beam of rays has illuminated the renal pelvis in the same plane as a typical longitudinal hemisection so that all the calyces together with the anatomical pelvis are projected in approximately the same plane.

This appears to circle round the vertebral column in a slight curve resembling a flat spiral. The upper calyces lie more posteriorly the lower more anteriorly the pelvis is displaced in a similar way. The upper part of the ureter continued this curve and then, somewhat lower down it bends fairly sharply backward this peculiar course speaks with some certainty for the presence of a horseshoe kidney.

As a supplement to the numerous earlier works on the same theme these observations and examples will help to determine the limits and possibilities of the new method. It must be pointed out that not all pictures obtained by intravenous pyelography will lead to an exact diagnosis. It can, however be said that the production of uroselectan B constitutes a considerable advance in increasing the reliability of the results.

IRRADIATION IN A CASE OF OSTEOGENIC SARCOMA, RECOVERY

SILVERWOOD MOORE, M.D. ST. LOUIS, MISSOURI

From the Department of Radiology, Washington University School of Medicine and the Edward Mallinckrodt Institute of Radiology

TO report an isolated example of a pathological condition and the result of its treatment is usually without excuse. If, however the pathological condition should be a malignant bone tumor and the treatment has resulted in cure then such a report becomes not only excusable but desirable. Furthermore if the successful method has been one which has given few or no favorable results previously the case assumes even greater interest. It is proposed to describe the radiation treatment of a case of osteogenic sarcoma and the results obtained. A few general remarks on bone tumors are included.

There is a vast amount of misunderstanding of every aspect of both benign and malignant bone tumors. Much of this is traceable to the lack of a uniform precise terminology as has been stated by others. The variability of development of the mesenchymatous tissues has refined pathological classification out of proportion to the essential basic differences to be found in the new-growths of bone. Causes which cannot be even surmised are operative in the metaplasia of the tissues of the connective tissue group. Bone fibrous and myxomatous tissue cartilage, alone or in combination mature or embryonic in type may compose bone tumors. But, however made up the origin is from the same primitive connective tissue type. If this fact is kept in mind the problem of bone tumors becomes simpler. The natural history of connective tissue and the tumors arising from it only become difficult to understand when too great an ingenuity is used to interpret it.

Contributing to the confused state of knowledge of bone tumors is fortunately their infrequent occurrence. Few physicians except in the larger clinics or hospitals have the opportunity for extended and intensive observation of these tumors. Coley quotes a British estimate of 400 osteogenic sarcomata in England in 1923. Codman is authority for the statement that in Massachusetts (1929) there was one case of bone sarcoma for each 100,000 of population.

The incidence of bone tumors in the group of hospitals allied to the Washington University School of Medicine has been 96 cases in 123,485 admissions in 18 years. The relative incidence of bone sarcoma to sarcoma of other tissues is 24:31. There have been 220 sarcomata of all types 96 of which were skeletal.

In spite of the efforts of the Registry of Bone Sarcoma of the American College of Surgeons and the writings of Bloodgood, Kolodny, Ewing, Geschichter and Copeland and others an astonishing ignorance of malignant bone tumors and their nature persists.

A sharp distinction should be made between tumors that are osseous by virtue of their origin and those that are osseous because of location. The first of these are strictly osteogenic tumors. Osteogenic has been frequently pointed out as an unfortunate term as it is a prolific source of confusion. Its correct meaning designates the origin of bone tumors from osteoblastic tissue. Often however the word is used in a way to imply the generation of bone. As this phenomenon, i.e. the development of new formed bone is encountered in a variety of conditions which are benign some of them even being physiological or normal repair processes it is of minimal diagnostic and prognostic value in the consideration of malignant bone tumors. Moreover in osteogenic sarcoma of the most malignant type new bone formation may be entirely lacking throughout most of the course of the disease. Osteogenic sarcoma is therefore defined as a malignant bone tumor that arises from true bone tissue. They are to be separated from malignant tumors arising from the tissues

Fig. 1. Roentgenogram made February 9, 1922. Antero-posterior view of right knee joint. Lateral view made same date on glass plate which was broken and hence is not shown.

Fig. 2. Photomicrograph of section showing undifferentiated cell type.

Figs. 3 and 4. Photographs of leg made after exploration, March 3, 1932.

which invest bone or those which are housed in bone. In the former class are subperiosteal fibrosarcoma and capsular sarcoma and in the latter endothelioma of bone (Ewing's tumor) the myelomata, angio-endotheliomata and the epithelial tumors of the jaws of dental origin.

Giant cell tumor should be referred to here but only because it is so often unfortunately designated giant cell sarcoma, this term implying malignant qualities. Indeed, especially when its treatment is being considered, giant cell tumor is often relegated to the same category as the malignant tumors that are found in bone. Thus arises much confusion as to methods and value of treatment. This disease is an independent pathological entity and its relationship to bone tumors is merely a matter of anatomical location.

The treatment of malignant bone tumors is by surgical removal, irradiation and Coley's toxins, either singly or combined. The oldest and most widely employed method of treatment is surgical removal of the tumor by amputation in the case of the extremities, and by excision in the case of tumors of the axial skeleton. The latter is, of course not always possible. At this point the limitations of the application of surgical treatment of osteogenic sarcoma appear.

The objective in the surgical treatment of osteogenic sarcoma is complete removal of the new-growth. Unless all of the tumor is removed recurrence will follow surgical attack. Success is

more apt to follow surgical operation on the extremities than those of the trunk. The weak point in surgical operation is the fact that at the present time there is no way of determining the exact limits of the tumor. Some value in this direction attaches to exploration of the vessels and marrow cavity in the involved member and locating the field of operation at a point where these structures are free from tumor. It should be remembered that sarcomatous extensions follow the paths of least resistance. These are the interior of blood sinuses and vessels, the loose tissues of the marrow cavity and the loose areolar tissue of the fascial planes and intermuscular septa. Since this is written by a radiologist, these points, though well known, are reiterated for the purpose of emphasizing the fact that radiotherapy must be directed to the tissues and areas enumerated to the ultimate limit to which the tumor might possibly extend. The necessity of this is either not understood or is neglected in radiotherapeutic methods. The impossibility of determining the extent of sarcoma is the reason of the failure of both surgical and radiological treatment of this disease. There is an advantage in the toxin treatment of bone sarcoma as compared with either surgery or irradiation. It reaches the ultimate limit of the disease with certitude because the circulation is its vehicle. Determination of the tumor limits for surgical or irradiation treatment is necessarily based on a very crude estimate

Figs. 5 and 6. Roentgenograms of March 10, 1932. Anteroposterior and lateral views of the tibia shortly after exploratory operation before irradiation.

Figs. 7 and 8. Roentgenograms of April 13, 1932. Anteroposterior and lateral views of tibia at the time deep X ray therapy was instituted.

It has been stated that of the therapeutic methods employed in bone sarcoma surgical removal is the oldest, the most widely used, and has resulted in the greatest number of recoveries. It is a more stabilized form of treatment and there is far greater unanimity of opinion as to the details of its application and the results obtainable than is the case with either the toxin or irradiation treatment of bone tumors.

The toxin treatment has not been as widely used as it deserves to be. One cannot read Coley's reports without drawing two conclusions. First, that in Coley's hands his toxin treatment has yielded more impressive results than can be found in any other method of treatment. Second, it should be more widely, skillfully and faithfully used than seems to be the case except in Coley's hands.

Of the three methods of treatment of osteogenic sarcoma, irradiation is the least understood and the most inconsistent in application and has the greatest diversity of opinions as to methods of use. This vagueness and uncertainty is due to the developmental state of radiotherapy. This is particularly true as regards X radiation. Here there has been constant change of method, apparatus, and technique of administration. This has been so diverse that it is impossible for one to evaluate the results of treatment of a few years ago as com-

pared with those of today. Fortunately, this is partly explained by the fact that there has been such great progress in the direction of greater efficiency of this agency. Even with radium there has been great variation in methods and views as to the application of this more stable agent. It may be added that there is no immediate prospect of the complete stabilization or standardization of radiotherapy.

There should be no therapeutic distinction between X irradiation and radium irradiation on the basis of any particular specificity of ray for pathological tissue though many authorities will dispute this statement. The object to be attained in irradiation is absorption of the correct amount of ray by the tumor tissue. This is at times achieved by radium and at others by the X ray. Frequently it is advantageous to employ a combination of the two for example distance irradiation by X ray following interstitial radium irradiation.

It is a deplorable fact that venal consideration sometimes determines the choice of the use of radium or X ray.

Irradiation of osteogenic sarcoma has been chiefly applied to the far advanced cases or as an adjunct to other methods of treatment. In the latter class of cases it is chiefly used for recurrences and metastases. In short, it is applied to unpromising material.

Fig. 9 Roentgenogram of chest made on June 1, 1922.

Ewing is authority for the following "yet some cases of osteogenic sarcoma recover under irradiation." Nevertheless, a review of the literature with this point in mind revealed not a single example of irradiation as the method of treatment in an early authentic example of osteogenic sarcoma.

The subject of this report, the history of which follows, came to treatment relatively early after the onset of the disease. When it presented itself it had the clinical radiological and histological characteristics of osteogenic sarcoma. The type of irradiation employed was first interstitial with radium element followed by application of "deep" X-ray.

CASE REPORT

S. W. Out Patient Department, No. A72030, white girl, aged 11 years, presented herself to the Washington University Dispensary February 2, 1922 complaining of swelling about the right knee. The family and previous history were of no moment. A month before entry patient fell and hurt the region of the right knee which gradually swelled and became painful on its inner aspect. Physical examination revealed only the condition about the right knee. There was a diffuse swelling of the upper medial aspect of the tibia. The knee joint was unaffected. There was slight tenderness to pressure. X-ray examination was made (Fig. 1). The Wassermann was negative. Pain became

Fig. 10 Roentgenogram of chest made on July 23, 1922.

severe and patient entered the Jewish Hospital, February 5, 1922. At this hospital the tumor of the tibia was explored and found to have the characteristics of malignant bone tumor. In spite of a prior consent, amputation was refused. Material for histological study was removed and it proved to be osteogenic sarcoma (Fig. 2).

The patient was referred to the St. Louis Children's Hospital for irradiation (Figs. 3, 4, 5, and 6). As the tumor had already been traumatized and manipulated by the exploratory operation it seemed that radium implantation could scarcely add to the hazard of mechanical dissemination of tumor cells. It was, therefore, decided to irradiate later distally. Accordingly over a period of 3 days 166 milligram hours of irradiation with radium element in needles was evenly distributed, as well as could be judged, throughout the tumor mass. A week later deep X-ray therapy was applied over both the lateral and medial aspect of the leg to the limit of toleration (Figs. 7 and 8). The patient was irradiated with heavy dosage of X-rays on four occasions from March, 1922, to April, 1923. She has been systematically observed and radiographed from the first observation up to the present time. At no time has there been evidence of pulmonary metastasis (Figs. 9 and 10).

On March 7, 1923 patient was found to be developing a bow leg to such an extent that corrective measures were indicated (Figs. 11 and 12). This deformity appeared to be due to arrested growth of the tibia in the zone which was the site of the tumor. There was arrest of bone growth on the inner half of the tibia, both interstitial and from the epiphyseal cartilage. A brace was applied to correct the bowing of the leg.

Routine examination of this patient was made on March 14, 1924. At that time the examination revealed a small collection of faintly calcified material lying medial to the inner tuberosity of the tibia. This increased to the extent noted in the examination of August 19, 1925 (Fig. 13).

Figs. 11 and 12. Roentgenograms of April 24, 1931. Anteroposterior and lateral views of tibia revealing condition of bone slightly more than a year after onset of disease. The bowing of leg is indicated.

Since that time the calcification has remained unchanged (Fig. 14).

Through an entirely fortuitous set of circumstances this patient had what appears to be the unique experience of receiving irradiation treatment for an early osteogenic sarcoma. According to the views of many writers, at least two things were done in this case which are contra indicated, namely, exploration of the tumor without amputation following and intratumoral implantation of radium needles. Under the circumstances as noted the radium implantation appeared harmless.

Biopsy is justified in suspected osteogenic sarcoma, for the diagnosis of this disease is at best a difficult one to make and few physicians have enough experience with it to permit of its early diagnosis on clinical data or even clinical and radiological data combined. Biopsy alone is not necessarily an accurate determinant of the nature of bone tumors. Coley's views on the importance of the gross appearance of these tumors as a factor in diagnosis has not received the endorsement it deserves. If biopsy and exploration is to be done on a suspected osteogenic sarcoma a plan of treatment should be formulated first and be capable of being immediately instituted if desired.

Kolodny has pointed out the fact that intensive irradiation may be highly injurious to surrounding healthy structures. Desjardins has reported a case with marked atrophy of the structures about the shoulder girdle in a case of osteogenic sarcoma (?) of the humerus after intensive irradiation. There

Fig. 13, left. Roentgenogram of August 19, 1931. Calcified material in soft tissue medial to tuberosity of tibia.

Fig. 14. Roentgenogram of July 23, 1932. Shows calcification stationary.

was also sclerosis of the humerus. In the subject of this report there is also marked sclerosis of the tibia. This change, however, seems to have regressed, the affected portions of the tibia assuming the nearly normal striated bone texture of Figure 14. At no time has there been evidence of injury to the knee joint.

CONCLUSIONS

Few conclusions can be drawn from this isolated case. It seems to show that intensive irradiation applied early in the course of osteogenic sarcoma may result in recovery for an extended period (10 years). Tumor exploration and biopsy can be done in this disease without necessarily disseminating it. The same statement applies to intratumoral radium implantation though the writer most emphatically believes that this should not be done unless the circumstances are extraordinary as in this case.

Though irradiation may do great damage to adjacent and overlying healthy tissue, in young persons they can revert to an approximately normal condition and remain so.

It is exceedingly difficult for a radiotherapist always to secure histological diagnosis, hence he is too often working in the dark and is ignorant of just what he is accomplishing. Prolonged observation of patients is next to impossible. Perhaps there are more favorable results in osteogenic sarcoma than is thought to be the case.

The writer wishes to express his appreciation of the kindness of Dr. Malvern B. Clepton for the privilege of observing and reporting this patient. This patient was originally

on Dr. Clopton's service at the St. Louis Children's Hospital.

PHYSIOLOGICAL REST AND THE PRESERVATION OF LOCOMOTION¹

VERNON L. HART M.D. F.A.C.S. DAYTON OHIO

THE fundamental and guiding principles of the prevention of deformity and the preservation of function of the apparatus of locomotion should interest both the general practitioner and the specialist. The orthopedic surgeon is primarily concerned in the correction of deformities and the restoration of function of the apparatus of locomotion and, as a teacher, he instructs his students in the underlying mechanical and physiological principles which will prevent deformity and disability. The orthopedist has little opportunity to apply practically these principles as compared with the other members of the medical profession. However he is more cognizant of their meaning and importance since too frequently he sees the crippling conditions which result from a lack of understanding and improper application of them. These principles were not emphasized to the medical student 20 years ago. Today they receive some emphasis and their application prevents many surgical hazards and gives much gratification. The field for their use is large and they are effectively applied as a part of the therapy for any disease or condition which may possibly terminate with partial or complete loss of the functions of the extremities and the spine. Paralyzes, burns, nutritional disorders, bone infections, joint infections, injuries (to nerves, tendons, ligaments, bones, joints, and muscles), the arthritides, congenital deformities and other less common problems may often require the intelligent use of the principles to be considered in this paper.

Collectively the principles may be termed as physiological rest. The principles of rest have been studied and practiced since the time of John Hunter (1728-1793). Sir Arthur Keith states in *Menders of the Maimed* that it was the custom of John Hunter to prescribe rest as a routine measure in the treatment of disablements of the motor system of the human body. John Hilton (1807-1878) regarded rest as the most powerful aid which the surgeon could bring to the aid of disordered tissues and Hugh Owen Thomas (1834-1891) made rest his creed and ritual. Rest as a part of the therapy for disorders of the apparatus of locomotion is at present too often neglected because of insufficient knowledge of its meaning. In general the conception of the term 'physiological rest' is incomplete and confused. The program of physiological rest will vary ac-

cording to the particular disorder but the underlying principles expressed in the following general outline are constant. The principles are mechanical and physiological; the therapy is applied anatomy and physiology.

Physiological rest

1. Surgery (manipulative or open) when indicated.
2. Fixation in the optimum positions—(a) optimum positions when restoration of function is anticipated (b) optimum positions for ankylosis.
3. Maintenance of the integrity of the neuromuscular, vascular and articular systems.

The writer believes that a therapeutic program as outlined will help the physician to understand more clearly the fundamental principles that are important in preserving the functions of locomotion, and it will make for order and clarity in the minds of the medical students as to treatment of diseases affecting locomotion.

Contractures and loss of function of the fingers and shoulder joint following treatment for Colles fracture are evidence that part 3 of the program outlined was neglected. Extensive scar tissue webs binding the chin to the base of the neck or the arm to the side of the thorax could be avoided if part 2 were properly included in the therapeutic program of treatment for burns. The period of disability and hospitalization of patients with hematogenous osteomyelitis could be reduced if part 1 of the program were adequately executed. A large list of illustrations could be presented to demonstrate that the reason for numerous

Fig. 1. Patient with extensive paralyzes of both lower and right upper extremity during the acute tender paralytic phase of anterior poliomyelitis. The affected extremities are immobilized in the optimum positions for restoration of function. Proper fixation will prevent contracture deformities.

surgical hazards and loss of function of one or more parts of the locomotor apparatus has been negligent application of one or more of the three phases of "physiological rest."

The principles of fixation vary according to whether restoration of function is or is not anticipated. Accordingly there are optimum positions for fixation when return of function is expected and optimum positions for ankylosis. The positions for fixation of fractures depend upon the type of fracture and the anatomical region fractured. It is not the purpose of this paper to review the numerous positions of fixation for all fractures but to emphasize the need of a clearer conception of the general treatment of fractures by means of physiological rest.

The optimum positions for fixation of the extremities and spine during the acute paralytic stage of infantile paralysis are shown in Table I. These positions are optimum because the lower extremities are in the most useful positions for the function of walking. The pelvis is on a transverse plane and the hips are abducted to favor the gluteal muscular mechanism which plays an important rôle in stabilizing the pelvis during the process of walking. The normal physiological curves of the spine are preserved. The shoulder is abducted and the elbow is flexed for the purpose of favoring those muscles which must function against gravity. The wrist and hand are immobilized in the physiological position of grasp with the thumb in the position of opposition and

TABLE I.—OPTIMUM POSITIONS FOR FIXATION WHEN RETURN OF FUNCTION IS ANTICIPATED (INFANTILE PARALYSIS ACUTE TENDER STAGE)

Shoulder

1. Abduction 90 degrees.
2. External rotation 45 degrees.
3. Anterior flexion (elbow in front of anterior axillary line).

Elbow

1. Flexion 90 degrees.
2. Supination.

Wrist

1. Extension 30 degrees (dorsiflexion).
2. Neutral as to radial and ulnar deviation.

Physiological position of grasp

Hand

1. Fingers in semiflexion.
2. Thumb in position of opposition.

Spine

1. Straight with the normal curves not exaggerated.

Pelvis

1. Transverse plane.

Hip

1. Abduction.
- Neutral as to rotation.
2. Neutral as to flexion and extension.

Knee

1. Straight with support under popliteal concavity.

Foot and Ankle

- Dorsiflexion 90 degrees.
2. Neutral as to inversion and eversion. Arches well supported. Toes side by side and extended.

the fingers semiflexed (Fig. 2). Failure to apply these principles results in the development of contracture deformities which cause partial or complete loss of function of the upper and lower extremities and the trunk, as demonstrated in Figures 3a and b.

Figure 3 demonstrates the principles of splinting for Erb's brachial plexus birth paralysis when return of function is anticipated. Flaccid paralysis resulting from lesions of the peripheral nerves should be immobilized in the position of relaxation as demonstrated in Figures 4a—4b. Relaxation of a partially paralyzed muscle facilitates restoration of function while stretching favors further paralysis.

Burns involving the axillary region should be treated with the arm abducted and externally rotated in order to prevent fixation of the arm to the thorax by scar tissue as seen in Figure 5.

Bowing of the extremities and disturbances of the normal weight bearing lines can be prevented

TABLE II—THE OPTIMUM POSITIONS FOR
ANKYLOSIS OF JOINTS

Shoulder

- 1 Abduction.
 - (a) Adult 45-50 degrees.
 - (b) Child 60-75 degrees.
- 2 External rotation—15 degrees.
- 3 Anterior flexion (arm in front of anterior axillary line)

Elbow

- 1 Occupation.
- 2 Right or left handed.
- 3 Flexion 90 degrees with hand in mid pronation.
Ankylosis of both elbows—one slightly more and the other slightly less than a right angle.

Wrist

- 1 Dorsiflexion 45 degrees.
- 2 Neutral as to ulnar and radial deviation.

Hand

- 1 Position of grasp altered by occupation.

Spine

- 1 Position in which normal curves are slight. Slight forward flexion of head and neck to accommodate walking and reading

Hip

- 1 Adult.
 - (a) Flexion 45 degrees sitting occupation.
 - (b) Flexion 15-35 degrees standing occupation.
 - (c) Abduction 5-10 degrees.
 - (d) External rotation 5 degrees.
- 2 Child.
 - (a) Flexion 35 degrees.
 - (b) Abduction 5-10 degrees.
 - (c) External rotation 5 degrees.
- 3 Age.
 - Occupation.
 - Degree of shortening

Knee

- 1 Occupation.
 - (a) Straight—standing occupation.
 - (b) Slightly flexed—sitting occupation.
- 2 Child—complete extension.

Foot and ankle

- 1 Plantar flexion 5-10 degrees (altered by sex and shortening of extremity)
- 2 Neutral as to inversion and eversion. Arches supported. Toes extended and side by side.

during the active phase of rickets if the infant is immobilized on a Bradford frame or in a plaster of-paris spica and not permitted to be weight bearing on the softened bones.

Deformity and loss of function of an anatomical part are frequently inevitable. Destruction and loss of function of the affected joint is the usual end result in joint tuberculosis. Gonorrheal arthritis, ankylosing atrophic arthritis, compound intra-articular fractures, and non specific joint infections not infrequently result in fibrous or bony ankylosis. Ankylosis of a joint may greatly

Fig. 3. Brachial plexus birth paralysis is best treated with the affected extremity immobilized in the optimum position for restoration of function as illustrated.

or only slightly interfere with the functions of the apparatus of locomotion. The degree of disability depends upon the position of ankylosis of the affected joint. Loss of function of the hand is minimum and slight if the wrist is ankylosed in the position of dorsiflexion but ankylosis of the wrist in extreme plantar flexion results in very marked loss of function of the hand. Ankylosis of the hip joint in one position may force the patient to walk with the aid of crutches while ankylosis in another position may be associated with only moderate disability. The positions of ankylosis which cause the minimum of interference with the functions of the apparatus of locomotion are known as the optimum positions for ankylosis and may be outlined as in Table II.

Figure 6 represents the proper application of the principles of fixation when ankylosis of the hip is anticipated in a child with infectious arthritis of the hip joint.

The optimum position for ankylosis of certain joints varies according to age, sex, and occupation. The knee during childhood, should not be ankylosed in flexion since with continued weight bearing the flexion deformity increases at the level of the epiphyseal discs. The position for ankylosis of the ankle varies in men and women because of the difference in the height of the heels of the shoes. The adult patient should always be

Fig. 4. A. Radial nerve neuritis with wrist drop. B. Should be treated with the wrist splinted in the optimum position for relaxation of the paralyzed muscles.

consulted regarding his occupation before the position for ankylosis is definitely determined.

The principles included in part 3 of the program of physiological rest are generally grouped under

Fig. 5. Note the preventable scar tissue web between arm and thorax complicating an extensive burn. Axillary burns should be treated with the arm in the optimum position for return of shoulder joint function (abduction and external rotation).

Fig. 6. The right hip joint immobilized in the optimum position when ankylosis is anticipated. Proper fixation will prevent ankylosis in poor functional position.

the heading of physical therapy. They include numerous measures which favorably influence the physiology of the various tissues which control the functions of the apparatus of locomotion. Assiduous attention to these measures often determines the success or failure of treatment. The integrity of the circulatory neuromuscular and articular systems can be maintained in the presence of certain disorders if mechanical and physiological principles are intelligently applied. These measures may be conveniently outlined as follows:

PHYSICAL THERAPY

- I. The normal stimulus of function
 - A. Weight bearing
 1. Partial
 2. Full
 - B. Active muscular contractions
 1. With joint movements
 2. Without joint movements
 3. Assisted
 4. Unassisted
- II. Elevation
- III. Massage
- IV. Heat—induced fever
 - A. Local
 - B. General—systemic
- V. Cold
- VI. Alternating heat and cold (contrast baths)
- VII. Electrotherapy
- VIII. Heliotherapy
- IX. Occupational therapy
 - A. Under water gymnasium or therapeutic pool

Stiff and useless fingers should never result after proper treatment of a Colles' fracture if the patient is instructed actively and completely to extend and flex the fingers several times daily while the fractured part is splinted. The same patient will not lose the functions of abduction and external rotation of the shoulder on the affected side if the patient is instructed actively and frequently to place the hand to the mouth and back of the head while the Colles' fracture is immobilized. These principles are expressed in a phrase which may be applied to most fractures—'actively mobilize the muscles while the fractured bone is immobilized.'

Muscles of an extremity can be actively contracted although the extremity is firmly immobilized in apparatus. This is often highly desirable in order to maintain muscle tone, to prevent atrophy and muscular contractures and to maintain the integrity of the neuromuscular and articular systems. Several days after surgical treatment for internal derangements of the knee joint the patient is instructed actively to contract the quadriceps muscle. Subsequent knee joint function depends upon the integrity of the extensor apparatus of the knee joint. Many patients who had torn semilunar cartilages treated surgically experienced continued disability because the quadriceps mechanism paralyzed by the local surgical shock, was not re-educated.

The principle of elevation is simple and obvious but the lack of its application is seen daily.

Restoration of function following a supra condylar fracture of the elbow as well as many other fractures is aided by active motions under warm water. The heat stimulates the circulation and the buoyancy of the water relieves much of the weight of the extremity and gravity as a result active motion is accomplished with less muscular effort and with less pain.

A child with residual paralysis of anterior poliomyelitis may be able actively to contract, exercise and develop partially paralyzed muscles under water but out of water the same muscles could not function against gravity and the weight of an extremity. Septic joints, hand infections, osteomyelitis, paralyzes fractures and other conditions affecting locomotion will often show remarkable improvement if treated under water at the proper time during the therapeutic program. The number of illustrations to show the practical applications of these various principles is unlimited while the vast number of principles involved in surgical judgment and surgical technique will not even be considered.

The purpose of this paper is not to consider the details of management of any stage of treatment of the many disorders of locomotion but to present a general outline of the program of therapy which will tend to diminish the number of preventable surgical hazards.

The three phases of the program of physiological rest and the numerous principles implied in each should guide the clinical course of all patients suffering with disorders of the apparatus of locomotion.

OVARIAN TERATOMATOUS CYSTS OCCURRING IN CHILDREN

Cecil P G Wakeley D.Sc. (Lond.) F.R.C.S. (Eng.) F.R.S. (Edin.) LONDON, ENGLAND

Surgeon to King's College Hospital and the Belgrave Hospital for Children, Consulting Surgeon to the Maudsley and Homemann Hospitals, etc. Honorary Professor, Royal College of Surgeons of England

IT HAS been estimated that of all tumors affecting the ovary 7 per cent consist of dermoid and teratomatous cysts. Such tumors are rarely met with before puberty, although they may occur at any age. McKee, when describing a case in a child aged 7 years which came under his care in 1899, stated that 52 cases only had been previously recorded. Since that time, however, further cases have been recorded but the total number at the present time is still under 100.

At the Hospital for Sick Children, Great Ormond Street, not a single case has been met with in the last 25 years, either on the clinical side or discovered at autopsy. At King's College Hospital 1 case only (Case 2) has been seen in 25 years and no other case is to be found in the postmortem records. At the Belgrave Hospital for Children, 1 case only (Case 1) has been seen in the last 25 years and no cases have been recorded in the postmortem files.

From the records of these three hospitals, dermoid and teratomatous cysts of the ovary are apparently very rare in young subjects. On account of their relative rarity I have deemed the following cases worthy of publication. Two cases have come under my own personal supervision, while the third case which was under the care of Miss M. Glen Bott, of Nottingham, to whom I am greatly indebted for kindly allowing me the opportunity of publishing it, was of especial interest as it was similar in many respects to one of my own.

Teratomatous cysts are frequently called dermoids, but such a designation is a misnomer and should be discarded. A dermoid is strictly speaking an inclusion cyst, the walls of which contain structures derived from the ectoderm only. The existence of such a cyst in the ovary has yet to be proved.

Teratomatous cysts contain elements derived from the ectoderm, in the form of skin or of its appendages from the mesoderm, represented by unstriped muscle, cartilage and bone and from the entoderm, exemplified by intestinal and respiratory mucous membrane.

The term "embryoma" is frequently used to designate these tumors, and is perhaps a more significant term than "teratoma." Both these

terms, however, are applied to a group of neoplasms composed of heterogeneous tissue elements.

A teratomatous cyst is always composed of two definite parts: (1) an intracystic rudiment in which representatives of all three primitive layers of the blastoderm can be demonstrated; (2) a cyst wall which encloses the embryonal rudiment.

These cysts are occasionally bilateral but are more usually unilateral. The mode of origin of such cysts has given rise to much speculation in the past, but up to the present time no theory concerning their causation is quite convincing. Probably the theory conceived by the late Professor Shattock is the most satisfactory. He suggested that an embryoma may be due to the fertilization of one of the primordial ova in the ovary of the developing embryo, the result being that the embryo gives rise to a second imperfect individual whose origin is not synchronous with itself but is of a later date.

The 3 following cases all occurred in young girls. The cysts were removed by operation, and a careful histological examination was made in each case.

CASE 1. Elizabeth M. aged 9 years, was admitted to the Belgrave Hospital for Children in May 1923 on account of a hard abdominal tumor which had been noticed for some 4 months previously. She was the eldest child of a family of four all girls. Her mother was 32 when she was born, and had been operated upon at the age of 25 for a right ovarian cyst. The child's mother when first she brought her daughter to the hospital, volunteered the remark that she thought her girl had the same trouble as she had had herself and therefore requested that an operation should be performed for its removal. This is the first case of a teratoma of the ovary occurring in both mother and child, which has been put on record.

When first seen at the hospital the girl was found to be an intelligent, well built and athletic child. She stated that she first noticed a lump in her abdomen shortly after Christmas, 1922, when lying in a bath. Previously to that date, she had no idea that there was a lump in her belly and it had caused her no trouble or inconvenience whatever.

On examination, a large hard tumor could be both seen and felt when the patient was lying down. The apparent size of the tumor was comparable to that of a large grapefruit. It was quite smooth and hard and was freely movable in the abdominal cavity. On pressing the tumor in an upward direction the patient complained of some pelvic discomfort. Rectal examination was negative. The growth of pubic hair was extensive, the breasts were well developed and appeared to be about the size of those of a girl at

Fig. 1. Drawing of teratomatous cyst of ovary. A section has been made through the center of the tumor (Case 1). The two main cysts are divided by a thick septum. Two large molar teeth can be seen in the upper cyst.

puberty. Menstruation had not commenced. There were no symptoms referable to the alimentary tract. The bowels were open daily without the aid of purgatives. As the girl was in her school net ball team she must have taken a considerable amount of strenuous exercise every week. The kidneys could not be palpated and the urine was normal. There were no symptoms of any pressure on the bladder.

On May 25 the abdomen was opened by a paramedian incision and a large right ovarian tumor was exposed. The tumor had a thick pedicle which was so long that it was quite an easy matter to deliver the tumor outside the abdominal cavity. The pedicle was clamped between two pressure forceps and the tumor removed. The pedicle was transfixed and the cut end was so carefully sewn over that no raw surface was left exposed. The uterus and other appendages appeared quite normal. The whole abdominal cavity was explored but no other abnormality could be discovered. The wound was closed in layers with interrupted sutures. The patient made a rapid recovery and was able to leave hospital 16 days after the operation.

She was brought up to hospital again in July, 1935, as she had had a period which lasted 4 days, but otherwise appeared normal in every respect. She remained under observation for some long time. She kept quite fit and well and although she was not yet 10 years of age, her periods occurred regularly. Whether the removal of the ovarian teratoma had an influence on the early menstrual history of this patient or not, is a moot question.

The tumor measured 4 inches across, and weighed just over a pound. It was hardened in formal solution and some 10 days later was subdivided by a median section.

Fig. 2. Microscopical drawing ($\times 25$) of the wall of the cyst in Case 1. The edge of the cyst is partially covered with thick stratified epithelium showing keratinization. The section exhibits two gland ducts, lined by high columnar epithelium and areas of dense leucocyte infiltration.

It was found to consist of two cysts, an upper and a lower (Fig. 1). The walls of the cysts were very thick and fibrous. Inside the upper cyst was a solid elevation on the summit of which two well marked molar teeth could be seen. The lower cyst contained thick mucoid fluid and on the inside, at one place, there was an irregular thickening which on section was found to be cartilaginous. No hair was found in any part of the tumor.

Microscopically the tumor exhibited the characteristics of a teratoma. The lining of the cyst was in places columnar dilated epithelium in others it was composed of stratified epithelium (Fig. 2). Sebaceous glands and also some nervous tissue could be seen. In other sections distinct areas of cartilage were found but in no part was there any evidence of bone. In all probability bone would have been found in the region of the molar teeth, but as the specimen was preserved intact, as far as possible, micro-

Fig. 3. Drawing showing one-half of ovarian teratoma removed in Case 5. Multiple cysts can be seen.

scopical sections were confined to the region of the cyst wall only.

CASE 5. Elsie B. aged 8 years, was quite healthy up to the age of 5 years, when she commenced to suffer from constipation and required purgatives three times a week at least. She was treated for constipation at several hospitals and dispensaries but her condition did not improve.

Apart from the constipation, she enjoyed good health, and was quite a bright and intelligent child. On November 30, 1931 she was seized with abdominal pain and vomited several times. The vomiting was followed by some loose motions. The pain lasted a few hours only. Shortly after ward she was playing with other children and appeared to be quite normal. The mother gave her a bath in the evening and then noticed a swelling in her abdomen, which she was quite certain had not been there before. The child was sent up to King's College Hospital where she was found to have a large, hard abdominal tumor about the size of a small coconut. It was movable from side to side, and slightly from above downward, but could not be displaced upward farther than the bend of the pelvis. The tumor appeared to be cystic in places. Since the appearance of the tumor the child's bowels had acted normally every day without the aid of any purgatives. Rectal examination was negative.

The girl was shown at a meeting of the Children's Section of the Royal Society of Medicine, on the 17th of November 1931, as a case of dermoid cyst of the ovary. The consensus of opinion, however was that the tumor was a mesenteric cyst.

The history of this case is all important since I came to the conclusion that the cyst had been within the pelvic cavity for several years, and was there the cause of the habitual constipation. When it suddenly rose out of the pelvis, as it undoubtedly did, it brought about a certain amount of shock which caused the child to vomit. If the tumor had slowly developed within the abdominal cavity proper the child's mother who bathed her every night, would certainly have noticed a swelling before. The subsequent relief of the constipation due to the diminution of pressure within the pelvic cavity is especially worthy of note.

On December 2, 1931 a laparotomy was performed under open ether anesthesia. The abdomen was opened through a right paramedian incision, and a large right ovarian cyst, weighing just over 2 pounds, was removed. The left ovary was normal. No other abnormalities within

Fig. 4. Microscopical drawings of different parts of the wall of the tumor in Case 5. Above, microscopical drawing showing dilated capillaries in dense fibrous stroma. Below, microscopical drawing showing thin layer of stratified epithelium opening on the surface of which is a sebaceous gland. Four hair follicles lying more deeply in the section can be seen. (X75)

the abdominal cavity could be found. The wound healed normally and the child was able to leave hospital 14 days after the operation.

When the tumor was cut through its center was found to be mainly cystic with a hard solid formation at one part (Fig. 3). Microscopical examination of the wall of the cyst demonstrated its teratomatous nature. A number of cysts of varying sizes could be seen. One of the larger cysts was lined partly by columnar ciliated epithelium, and partly by a thick layer of stratified epithelium which, however did not show much tendency to the production of keratin. Sebaceous glands in association with this stratified epithelium were present (Fig. 4). Some of the cysts had lost their epithelial lining, but some, especially the smaller ones, were lined by columnar or cubical epithelium. Some of the cysts contained a homogeneous pink-staining material resembling thyroid colloid, otherwise no definitely recognizable thyroid tissue was present. There was ample evidence

of nervous tissue and several areas of calcification were found. The solid portion within the cystic cavity was found to contain hair, cartilage, and bone.

A very similar case to the foregoing was recorded by Meigs in 1899 in a girl aged 10 years. An abdominal swelling was noticed by the child's mother when she was undressing her. When the girl was examined at the hospital the swelling was thought to be a distended bladder. Catheterization was performed but a few ounces only of urine were withdrawn. Operation was performed and a twisted ovarian teratoma which contained sebaceous material, cartilage and bone was removed.

A correct diagnosis of these cases seems to be one of supreme difficulty and almost every variety of abdominal tumor has, at one time or another, been suspected without the real condition having been recognized.

CASE 3. Agnes W. aged 9 years, was admitted to the Children's Hospital, Nottingham, on the 31st of October, 1931 under the care of Miss M. Glen Dott, complaining of attacks of abdominal pain. The symptoms commenced insidiously in March, 1931. She complained of pain which had no relation to food but was accentuated by walking. The seat of the pain was situated just above the pubis. It was not relieved at night time, and she suffered from frequency of micturition. The bowels acted normally and there was no history of vomiting.

On admission to hospital, the patient was found to be a well developed and healthy looking girl. A pear-shaped swelling could easily be palpated in the abdomen. It was movable from side to side, and slightly upward and downward. It was dull on percussion, but not tender. Rectal examination was negative.

An operation was performed through a subumbilical paramedian incision. A large right ovarian cyst was removed, measuring 4½ by 5 inches. The left ovary was slightly larger than normal. The abdomen was closed in layers, and the patient made an uninterrupted recovery and was discharged from hospital on November 11, 1931.

The cyst was unilocular with a smooth wall. Situated near the base of the cyst was a definite, hard, intracystic elevation covered with stratified epithelium. Beneath the stratified epithelium, a single tooth was found to be embedded in a matrix of bone and cartilage. There was a considerable amount of hair and sebaceous material which provided an embedding medium in which all the tissues were glued together in a mass.

McKee recorded a case in 1900 in a girl, aged 7 years, where an abdominal tumor was thought to be a sarcoma of the kidney. Operation proved it to be a cystic swelling of the ovary containing

skin, sebaceous material, cartilage, and bone. In some of the early cases which are recorded tapping of these swellings was carried out in some cases because operative interference was not permitted by the parents of the child. Alcock in 1871 and Black in 1892 record cases where tapping was performed followed at a later date by removal of the tumor.

Owing to the systematic medical examination to which school children are now subjected it is very unlikely that ovarian cysts in young subjects will in the future, be allowed to assume any large size.

LATERAL ABERRANT THYROID GLANDS

STANLEY E. LAWTON M.D. CHICAGO

From the Department of Surgery of Rush Medical College of The University of Chicago, and Presbyterian Hospital of Chicago

TUMORS of the neck arising from lateral aberrant thyroid glands are rare and I have been able to find but 49 cases in the literature. The group as a whole has long been recognized. Albert von Haller in 1779 first observed anomalously placed islands of thyroid tissue in the neck. In 1839 Albers referred to misplaced thyroid tissue as accessory thyroid glands. Gruber in 1845 reported 2 cases and in 1849 a monograph accurately describing accessory thyroids, was published from Milan. In 1850, Stanley of England made the first extirpation of an aberrant thyroid gland. Occasional reports of clinical cases appeared up to 1897 when de Boncourt collected 15 cases of accessory lingual thyroids. A few years later Storr, Murphy and Schragar made extensive clinical studies.

The importance of lateral aberrant thyroid glands demands the interest of the embryologist and pathologist as well as the clinician. Embryologically their origin and development is much discussed but far from settled. Pathologically they are greatly influenced by the activities of the thyroid gland. They also show a distinct tendency to malignancy. Clinically their diagnosis is difficult and their prognosis favorable.

ORIGIN

Several theories have been advanced to explain the formation of lateral aberrant glands, these changing from time to time as additional information has been brought to light on thyroid embryology. It was once thought (Hls, Born, Prenant and others, that the thyroid originated from two sources, namely a median portion from the floor of the pharynx and two lateral portions from the lateral outpouchings of the pharynx. At that time it was possible to explain the presence of lateral thyroid tissue by assuming fusion of the lateral and median portions of the gland had failed to take place and as a result lateral rests remained in the neck.

Later following the discovery of the origin of the parathyroid glands from the third and fourth branchial clefts it was thought that the thyroid originated entirely from a single median anlage caudal to the anterior portion of the rudimentary tongue and that fusion played no rôle in its development. This theory necessarily discounted the belief that lateral rests were due to unfused thy-

roid tissue. More recently the so called fifth pouch, or ultimobranchial body has been claimed to play a part in thyroid development but upon this subject embryologists give decidedly conflicting opinions.

With the embryology of the thyroid still unsettled the origin of lateral aberrant thyroid glands likewise remains disputed. At present, evidence points strongly toward the origin of the lateral aberrant thyroid from the fifth pouch or ultimobranchial body. This theory is supported by Leech and his co-workers as follows: "The thyroid in its development is constantly associated with the migration and fusion of epithelial cells derived from the so called fifth pouch or posterior outpocketing of the pharyngeal complex (the ultimobranchial body) these epithelial masses may vary considerably in number and position the lateral aberrant thyroid glands tend in a high percentage of cases to undergo papilliferous and cystic degenerative change, a lesion never associated with lingual thyroid tissue. These facts, it would seem, serve to identify these tumors as a specific group and to account for their origin on sound embryonic evidence."

SYMPTOMS AND DIAGNOSIS

Many lateral aberrant thyroids produce no symptoms. As they increase in size they may cause the patient to consult a physician on account of swelling in the neck. Few produce sufficient pressure on the trachea and vessels of the neck to cause symptoms. Their growth is slow over a period ranging from several months to several years without signs of thyroid disease. They are usually situated in the anterior triangle of the neck and may occur as single tumors or as a chain of nodules. On palpation they are not tender and may be firm or soft in consistency. There are no constant clinical characteristics to differentiate lateral aberrant thyroid glands from tuberculosis, lymphadenoma, metastatic carcinoma, Hodgkin's disease or other conditions which may give rise to tumors of the neck consequently diagnosis is extremely difficult and rarely made. As an aid in differentiating these tumors of the lateral aberrant thyroid glands from other enlargements of the neck, Schragar has emphasized the following: (1) The tumor is likely to increase in size at puberty. (2) It tends to fluctuate in size

during menstruation. (3) It tends to become cystic. (4) It is usually unilateral if solid not greater than the size of a mandarin orange. (5) It is of slow growth, smooth and if not cystic of soft consistency.

PATHOLOGY

Briefly, lateral aberrant thyroid glands may be single or consist of a chain of glands connected by strands of thyroid tissue. In size they may vary from a few to 10 or more centimeters in diameter. They are encapsulated in a very vascular reddish green capsule and are firm or soft depending upon the amount of cyst formation which has taken place. Often they resemble normal thyroid tissue. Microscopic sections show a marked papillary growth of columnar epithelial cells in a vascular connective tissue stroma with evidence of slow growth as manifest by calcification, hemorrhage, hyalinization of stroma and cystic degeneration. The tendency of these tumors to undergo malignant degeneration is great and it is not uncommon to find mitotic figures and other signs of malignancy in what may otherwise appear to be a benign tumor.

During the past 10 years 3 cases of tumors of aberrant thyroids have been observed in the Presbyterian Hospital. These patients have been followed for 10, 9 and 7 years respectively. One of the patients subsequently developed marked hyperthyroidism from which she made a good recovery after subtotal thyroidectomy. Another writes that she is in excellent health and has had no illness since her operation. The third cannot be located at the present time. He was in good health for 7 years after his operation.

REPORT OF CASES

CASE 1. I. J., a woman aged 30 years, entered Presbyterian Hospital complaining of a tumor of the left side of the neck which had been present for several years gradually increasing in size during this time but with a more rapid increase during the past 6 months. She had no other subjective symptoms, the tumor had caused her no pain, and she stated that her general health had always been good. During childhood she had had measles and chickenpox and at age 17 years, an appendectomy. Her father, mother, two sisters, and a brother were living and well and no history of tuberculosis, malignancy or thyroid disease in the family was known.

The patient was a well developed, well nourished woman with a tumor mass behind the angle of the left jaw about the size of a hen's egg. On palpation the tumor mass was found to be medial to the upper portion of the sternomastoid muscle. It was firm, freely movable, showed no redness, and was not tender. The thyroid gland was palpated in its normal position. The teeth were good, the tonsils showed no infection, the heart borders were normal. There was an appendectomy scar in the right lower quadrant of the abdomen. Reflexes normal.

The urine was normal, the hemoglobin, red, white and differential blood counts were normal. X ray picture of the

Fig. 1. I. J. Showing extensive growth of cuboidal epithelial cells arranged in papillae and alveoli.

chest showed a small, old, healed tuberculous process of the left apex.

Under local anesthesia, an incision was made in a vertical direction through the skin and fascia. The tumor mass was exposed and carefully dissected out.

The specimen consisted of a mass measuring 4 by 3 by 2 centimeters. It was red and rather firm. The surfaces made by sectioning were moist, reddish brown and in portions resembled normal thyroid tissue while in other areas the tissue was soft and friable and contained small cysts. Microscopic sections showed extensive growth of cuboidal epithelial cells arranged in papillae and alveoli. The connective tissue was slight in amount. There were several fairly typical acini seen (Fig. 1).

CASE 2. G. P. E., a man aged 32, entered Presbyterian Hospital complaining of a swelling in the left side of the neck of 7 years duration, which had been gradually increasing in size during these years but had caused him no pain or discomfort in any way. During the past 3 months he noticed the increase in size of the tumor more than previously. During childhood he had had measles and mumps and an occasional sore throat. His father and mother were living and well. There was no history of tuberculosis, carcinoma or thyroid disease in the family.

The patient was well developed and well nourished. A firm, movable tumor about the size of a plum was found on the left side of the neck posterior to the angle of the jaw. Below this was a second tumor of the same description about the size of a hazel nut and along the anterior border of the sternomastoid muscle about 2.5 centimeters above the clavicle was a third tumor the size of a small plum and of similar consistency. The thyroid gland was palpated in the normal position. The tonsils were absent, teeth good, heart borders normal. A slight systolic murmur was heard over the apex. Pulse was regular rate 72. Blood pressure was 102 systolic, 70 diastolic. The lungs were normal. No tenderness or masses were noted in the abdomen. The reflexes were normal.

The urine was normal, the hemoglobin, red, white, and differential blood counts were normal. Blood Wassermann

Fig. 2 G. P. E. Showing papillary growth of cuboidal epithelial cells which in certain areas suggest malignancy.

Fig. 3 M. B. Showing marked growth of cuboidal epithelial cells in papillary and cystic formation.

was negative. X-ray examination of the chest showed a slight increase in hilar shadows but otherwise was negative.

Under ether anesthesia, an incision was made along the anterior border of the left sternomastoid muscle and seven glands were removed from beneath the muscle in its course through the neck.

The specimen consisted of seven nodes of various sizes, the largest being 5 centimeters in diameter. They were red and firm. Surfaces made by sectioning were moist, reddish brown, and contained a few small cysts in which there was a brown fluid. Microscopic sections showed marked papillary growth of cuboidal epithelial cells growing on a markedly vascular connective tissue stroma. In the base of some papillae were found groups of apparently normal acini lined with cuboidal epithelial cells and filled with colloid. The papillary structure in certain areas suggested malignancy (Fig. 2).

CASE 3. M. B. a woman, aged 36 years, entered Presbyterian Hospital complaining of a swelling in the left side of the neck present for 15 years or possibly longer. This swelling was first noticed during puberty and seemed to be slightly larger during her menstrual periods. Aside from this slight fluctuation the mass had not changed in size to any noticeable extent. She had reduced 35 pounds by dieting a year previous to her admission to the hospital. Since that time the swelling had been noticed by her friends and she had been quite conscious of it. She thought at times she had a slight choking sensation due to pressure of the tumor. Her general health had always been good. She had had chickenpox during childhood and an attack of influenza 6 years previously. A dilatation and curettage had been done following a miscarriage. There was no history of other pregnancies. Patient's husband had died of malaria. Her father, mother, one brother and two sisters were living and well and there was no history of tuberculosis, carcinoma or thyroid disease in the family.

The patient was a well developed, well nourished woman with a tumor mass about 2.5 centimeters in diameter on the left side of the neck anterior to the middle third of the sternomastoid muscle and a second tumor slightly smaller

at the angle of the jaw. On palpation these tumors were slightly soft, freely movable and not tender. Apparently there was no pressure being exerted by these on the trachea. The thyroid gland was palpated in the normal position.

The tonsils were not infected. The heart borders were normal, no murmurs were heard. Blood pressure was 120 systolic, 85 diastolic. The pulse was regular, rate 84. The lungs were normal. No masses or tenderness were noted in the abdomen. The reflexes were normal.

The urine was normal, the hemoglobin, and the red, white and differential blood counts were normal. Blood Wassermann was negative.

Under local anesthesia, an incision was made along the left sternomastoid muscle and the two tumor masses were removed by careful dissection.

The specimen consisted of two masses, each measuring approximately 4 centimeters in widest diameter. The tissue was red brown and firm for the most part, having a few small soft areas. The surfaces made by sectioning were moist and red brown. In the soft areas considerable brown fluid and small cysts existed. Microscopic sections showed marked cuboidal epithelial growth in papillary and cystic formation. The connective tissue was considerably increased and vascular (Fig. 3).

TREATMENT

In any case of suspected aberrant thyroid, the presence of a thyroid gland in its normal position should be determined. Once this has been established all doubtful masses in the neck should be removed. It is well to remember that pathology in the thyroid gland proper may cause enlargement with changes of the associated aberrant gland and in these cases it is well to proceed with considerable care. The location of these glands makes injury to the spinal accessory nerve and jugular vein easy. Another common complica-

tion is profuse bleeding. Because of the cystic structure of these glands aspiration has been attempted but this should not be done for it is both useless and not without danger. Following surgical removal all patients should be subjected to a series of X ray treatments such as are given for malignancy even though the tumor appears to be benign. These postoperative X ray treatments are of great importance as these tumors are radiosensitive.

SUMMARY

The tendency of lateral aberrant thyroid glands to undergo malignant degeneration has already been called to attention repeatedly but so important is this fact that it cannot be overemphasized. Although to all appearance these glands may be benign they have been known to recur after removal and produce metastases. That generally accepted benign tumors of the thyroid such as enchondromata and myxomata may become malignant is well known and years ago Cohnheim called attention to metastases arising from adenoma gelatinosum of the thyroid a benign tumor. Hinterstoißer in an extensive study of carcinoma of aberrant thyroid tissue observed that carcinoma of aberrant glands is less malignant than carcinoma of the thyroid gland proper. Recently Leech and others after a careful study of malignant tumors of the thyroid have pointed out the similarity between papilliferous adenomata of the thyroid and tumors of lateral aberrant thyroid tissue suggesting the possibility of a single origin for both groups of tumors from pharyngeal epithelial rests of the fifth pouch.

CONCLUSIONS

1 Lateral aberrant thyroid glands are extremely rare. They are of great clinical as well as of embryological and pathological importance. They are difficult to diagnose and tend to become malignant but with good surgical therapy they offer a relatively good prognosis.

2 In the presence of a thyroid gland in its normal position, suspected masses in the neck should be removed. X ray treatment should be given following removal in all cases.

3 Three additional cases of lateral aberrant thyroid glands are presented.

RICHTER'S HERNIA

RICHARD B. CATTELL, M.D. BOSTON, MASSACHUSETTS

From the Lary Clinic

RICHTER'S hernia is a rare unusual type of hernia. In spite of its rarity, an understanding of its pathology and the symptoms associated with it is important since any delay in recognition may result in very serious consequences. While Richter's hernia is a form of strangulated hernia, it is characteristically associated with partial intestinal obstruction rather than with complete obstruction which is usually present in strangulated hernia. Richter's hernia may be described as a hernia in which only a part of the circumference of the bowel is engaged and strangulated and this involved portion may rapidly become gangrenous although the lumen of the gut remains open to some degree. The portion of the engaged bowel resembles a small diverticulum of the wall (Fig. 1). Only those hernias that meet the description given should be included under this name.

In the early literature there was much confusion concerning this type of hernia, since many types were reported under this name. For instance, cases of small hernia, partial enterocoele, incomplete hernia, pinching hernia, Littre's hernia and the like have been reported as Richter's hernia. After an exhaustive review of the early literature Treves found 80 cases, in 53 of which the reports were complete enough for satisfactory identification and study. He included 4 operative cases of his own and gave a clear clinical picture of this condition. Three of his patients died after operation while the fourth in whom previous to operation a reduction of the hernia had been done *en masse* recovered following operation.

In 1700 Littre described 3 cases in which only a portion of the bowel wall was found in the hernia sac 2 of these were hernias later recognized as involving Meckel's diverticulum but the third could not be identified from his report. He believed that these diverticula were the result of the intestinal wall being pulled out into a sac. It was not until 1815 that Meckel described the diverticulum that now bears his name thus explaining the true nature of Littre's 2 cases. The first complete scientific description of this type of hernia was made by Richter in 1778. He described this form of hernia as a small rupture.¹ In his book on hernia, one chapter concerned the diagnosis and

treatment. He recognized that the wall of the involved gut was made up of the same layers and structure as were present in the intestinal wall, a condition not present in the diverticulum later described by Meckel. In considering treatment, he recommended, if gangrene had not appeared, reduction aided by dilatation of the ring with a hook, but if gangrene was present he believed that reduction was dangerous and that resection should then be done. Treves suggested that this type of hernia be called Richter's hernia in order definitely to identify it and to differentiate it from the hernia of Littre and other forms. The earliest report Treves was able to find was that of Guilielmus Fabricius Hildanus in 1606.² In the fifty-fifth observation of his first one hundred surgical cures, he described the case of an elderly woman who had a strangulated hernia which discharged into the groin, after which the patient had complete relief of symptoms. The intestinal fistula thus formed remained open for only 2 months following the scarification of the swelling. It then healed and the patient made a complete recovery. While the exact relation of the bowel to the hernia was not observed, the fact that the fistula closed indicated that only a portion of the bowel wall was in the hernia.

In 1809 R. S. Fowler reported under the title "Partial Enterocoele" 2 cases with this condition. He again made an exhaustive review of the literature and included a full bibliography in chronological order including 94 references. He presented an excellent clinical picture of the condition which was similar to that presented by Treves. R. H. Fowler in 1913 described 2 cases, one involving the caecum and the other the appendix. A review of the literature after 1809 was made by Rhodes in 1928. He was able to find 45 additional references since Fowler's report in 1809 and reported the histories of 3 patients with true Richter's hernias and 3 patients with a knuckle of small intestine in ventral hernias. The confusion which was present in the early literature was again evident in Rhodes' report since many of the reports that he included were of Littre's hernia. Bisell reported 2 additional cases in 1929, while Orr added 1 in 1930. After a review of the old and new literature on this subject, it will be seen that little attention has been

¹This book was obtained from the Library of the New York Academy of Medicine.

²This book was obtained from the Boston Medical Library.

paid to it since 1899 few reports were found, only 14 operations for this condition being reported. This by no means represents the actual incidence or number of patients seen and treated. So little attention has been given the subject that undoubtedly many patients are treated for simple strangulated hernia. Many of the standard text books in surgery do not mention the subject but we believe it is sufficiently important to report the cases seen.

CASE 1. An American laborer 60 years of age was examined in March 1927. He had been well until 24 hours previous to this examination when he developed a pain in the left lower quadrant. On the day that he was seen he had vomited several times. He had not been aware that he had a hernia. On physical examination he appeared to be acutely ill. His tongue was clean and there was no fecal odor to his breath. The abdomen was soft throughout, there was no visible peristalsis and no distention. A small swelling about 2 centimeters in diameter in the left groin could not be reduced. There was localized tenderness over the swelling. Operation was performed (Dr. H. M. Clute) 24 hours after onset, incision being made directly over the femoral ring. When the sac was opened, a segment of bowel was seen engaged in the ring (Fig. 2). The sac was purplish blue in color. The nature of the hernia was recognized as of the Richter type. The first incision was left open, the abdomen was opened with a left rectus incision, and the gut was reduced following enlargement of the hernia neck. The circulation appeared to return to this small involved portion although a small constriction ring remained. The area was then inverted without interfering with the lumen and the abdomen was closed in layers. The hernia was repaired in the usual anatomical fashion. This patient made an uneventful recovery and is now well, 5 years after operation.

CASE 2. An American farmer 63 years of age was seen in October 1930. He stated that several days previous to the examination his bowels had been constipated. A cathartic had not given any results. Two days before he developed a colic-like pain in the epigastrium which was localized just above the umbilicus. This pain was so severe at that time that one-quarter grain of morphine was given. He vomited once on this day. The following day the pain, still localized in the same area, recurred with about the same severity and again morphine was given. The patient was given an enema with fair result as to the elimination of gas, but it gave him considerable pain. Nausea persisted but there was no further vomiting. No blood or mucus had discharged from the rectum. Six years previously patient had had an abscess in the right groin which was incised. There had been no recurrence of infection in this area and no swelling had been noticed.

On physical examination patient appeared to be strong, well developed, but to have lost considerable weight. His tongue was dry and clean and his breath was not fecal. On abdominal examination there was found a moderate general distention but no spasm and no masses. A fluid wave could be demonstrated. There was no visible peristalsis. A small mass about 1 inch in diameter was present in the right femoral region. No impulse was obtained when the patient coughed. No attempt was made to reduce the mass, which was not tender on pressure. A healed scar was noted in this area. Rectal examination was negative. The white blood count was 13,000, the temperature and pulse were normal. A diagnosis of partial intestinal obstruction was made. It was thought that the condition was of malignant origin, probably arising in the colon. At operation

Fig. 1. The size and nature of Richter's hernia of the small intestine are represented diagrammatically. The involved portion of the gut is always on the side opposite the attachment of the mesentery a. Only a small portion may be involved. If very small no symptoms of obstruction are present, yet gangrene may occur. b. A pouch of this size results in partial intestinal obstruction. c. When over one-half of the bowel circumference is involved an intermittent partial obstruction or complete obstruction may result. This is in agreement with Scarpa's observation that when two-thirds of the intestine is strangulated complete obstruction results.

(Dr. R. D. Cattell) the abdomen was explored and it was noted that the entire large bowel was normal while the small intestine was moderately dilated and thickened. In the right femoral area a portion of the ileum was found strangulated in a small femoral hernia (Fig. 3) of the Richter type, so that the wall of the intestine was firmly engaged but the mesenteric border was free leaving the lumen somewhat narrowed so that it produced an intermittent partial obstruction. The femoral ring was enlarged so that the intestine could be freed. The color returned to the strangulated portion although a circular constriction remained, thus obstructing the lumen to about one-third of its normal caliber. The engaged portion appeared viable. Further inspection of the femoral hernia from within showed that the appendix was firmly engaged beneath the former position of the Richter hernia and was included in and adherent to the sac. In order to free the appendix the sac was inverted and appendectomy was performed. An intra-abdominal repair of the hernia by means of a pursestring suture to obliterate the neck was then done. An enterostomy was then performed 6 inches proximal to the strangulated area of the bowel. The patient's condition remained satisfactory throughout the operation. On the third day after operation he developed severe abdominal pain with a high elevation in temperature followed shortly by death.

Fig. 1. Case 1. The femoral sac has been opened thus exposing the strangulated intestine and showing this to be a hernia of the Richter's type. Laparotomy was done and the hernia reduced.

These reports show the difficulties of diagnosis. In the first patient there was no evidence of obstruction or of strangulation. We believed that the femoral hernia was the cause of the symptoms, the possibility of a Richter's type of strangulated hernia was not thought of until it was demonstrated at operation. In the second patient an intestinal obstruction was evident but the relation to a possible right femoral hernia was not appreciated until the abdomen was opened. This case is of particular interest in view of the fact that the abscess in the right groin 6 years previously may have been an acute appendicitis. The presence of the appendix in the sac and the dense adhesions may have been factors in the causation of the Richter's hernia. As an inguinal gland was present over the femoral hernia in this patient, it is possible that the abscess may have been related to an adenitis. At operation the strangulated bowel appeared to us to be viable, but undoubtedly the patient died from a peritonitis resulting from the rupture of the strangulated area in spite of the fact that an ileostomy had been done above the obstruction.

In 1906 Burpitt reported the case of a patient with identical findings. In his patient the appendix was present in the right femoral hernia and was non-strangulated but above it there was present a Richter's hernia of the ileum with strangulation. His patient had had a partial obstruction for a month with acute symptoms of 24 hours' duration. Operation was followed by recovery.

A review of the reported cases reveals common findings. This form of hernia occurs more often

Fig. 2. Case 2. A loop of terminal ileum is seen partially engaged in a femoral hernia. Partial obstruction is present with the proximal loop of bowel being distended. An out line of the cecum and appendix is shown with the appendix incarcerated in the femoral hernia beneath the ileum. The previous incision scar in the femoral region is not shown.

in women than in men and only in adults (Rhodes reported a case in a 3 weeks old negro baby the only exception). The average age is 53 years. The femoral ring is the usual site this being the region involved in about 90 per cent of the cases. The inguinal region is the next most frequent site, in rare instances, this type of hernia is found in the umbilical obturator epigastric and intra abdominal regions. Richter's hernia is more apt to occur in conjunction with a long standing reducible hernia than with one of recent onset or one that is irreducible. At times no swelling can be felt in the ring although there can usually be seen or palpated a small tumor varying in size from that of a hickory nut to that of a hen's egg. The terminal ileum is usually the portion of the bowel that is strangulated. Three patients were found in whom the jejunum was involved and one with the colon in the sac. The most common form is one in which the terminal ileum is involved in the right femoral canal. In this form, only a small portion of the circumference of the bowel is involved and rarely is there a complete obstruction (Fig. 1). The outer portion of the bowel, away from the mesentery is always the portion of the

ileum involved so that the general circulation of the bowel is not impaired.

In only one-third of the patients are the symptoms typical of a strangulated hernia with severe obstruction. In the presence of a complete obstruction a mass is usually palpable which is distinctly tender locally and is associated with cramp-like pain in the lower abdomen. Persistent nausea, fecal vomiting, hyperperistalsis, constipation together with the general manifestations of shock are the rule in this minority group. At times a persistent diarrhoea is present but rarely is there mucus or melena present. These patients present such typical pictures of complete intestinal obstruction that operation will be advised early and the results will be fair. While the nature of the cause of the obstruction may not be recognized before operation it will be demonstrated at operation.

By far the majority of the patients (that is two thirds) however have mild and indefinite symptoms suggestive of only partial or beginning intestinal obstruction. These are the ones in which only a small portion of the circumference of the bowel is strangulated. It is quite important to recognize such cases early since gangrene and rupture of this portion of the bowel may occur early and the patient may show no serious general response and no evidence of serious obstruction. Fecal vomiting in these patients is not common and fair results can be obtained in the elimination of gas and fecal matter by means of enemas at a time when local gangrene of the gut is present. A mass may or may not be present but if found is of great importance in making a diagnosis. After the first few hours of strangulation local tenderness may be absent and the pain, if present, may be far removed from the point involved. It is in this last group that the operative mortality is very high since operative interference is usually delayed.

As shown in the reported cases, diagnosis is very difficult in only 50 per cent could intestinal obstruction be made out. Diagnosis is made difficult also since in only one half of the reported cases has a palpable mass been present. As our knowledge of this type of hernia increases, diagnosis will be more easily made and the condition more often suspected in patients with femoral hernias presenting symptoms too of partial intestinal obstruction.

The mechanism acting to produce a Richter's hernia is not the same in all cases so that all cases cannot be satisfactorily explained on the same hypothesis. Many times such hernias are associated with old reducible hernias with adherent

bowel and doubtless such adhesions are frequent causative factors. In several instances of Richter's hernia, the case reports show that the hernias have been precipitated by forceful taxis. In addition the hernia has at times been associated with reduction of a hernia *en masse*. Treves reported 4 such early occurrences. Pearse recently advised against the use of taxis because it may cause reduction *en masse*. From the report of cases it would seem that taxis has caused the production of Richter's hernias in several instances. Pressure produced by a truss over the area of the incarcerated bowel may also contribute to the production of a Richter's hernia. Increased abdominal pressure in the presence of a hernia sac has frequently been described as a possible cause. With an incarcerated segment of bowel the normal peristaltic waves in other instances may well free the major portion of the bowel leaving a small diverticulum like portion remaining.

In Richter's hernia the sac is usually small and this factor prevents the engagement of the entire circumference of the bowel. The condition of the strangulated portion of the bowel wall depends on how long strangulation has been present and the size of the neck of the sac. In many of the earlier cases in which gangrene was present subcutaneous rupture led to fecal fistulae. In most of these the fistula persisted in only a rare case did the fistula close spontaneously (Hildanus). Not infrequently the presence of an enlarged tender gland the result of an inguinal adenitis over the hernia sac, has made it difficult to recognize the underlying condition. Of 38 cases of femoral type hernia, collected by Treves, 7 cases had such enlarged glands of the groin.

TREATMENT

The treatment of Richter's hernia is of course surgical. Operation should be done as soon as possible in order to avoid gangrene. In all cases of intestinal obstruction, either partial or complete the usual sites for hernia should be palpated. If the diagnosis is made so early that strangulation is not severe and if after observation circulation to the part is shown intact, simple reduction of the involved portion is sufficient. If the strangulated portion is small and has the form of a gangrenous pouch or diverticulum, it may be plicated or turned in without too great reduction in the lumen. This was done in Case 1 reported in this paper. If larger portions of the bowel are involved resection of the involved loop should be carried out with an end-to-end anastomosis. It is probably advisable to do an enterostomy above the inverted portion or anastomosis to relieve

local pressure, particularly if obstruction has been present.

In the nearly moribund patients two procedures may be carried out. In the first an enterostomy is done the gangrenous portion of the gut being left engaged and a local incision made over the hernia as indicated. This plan is suggested by the fact that when a fecal fistula has formed spontaneously 30 per cent of the patients recover without operation. In the second plan the involved loop is brought out after the plan of Mikulicz and the fistula is closed when the general condition of the patient has improved. Objections can be raised to either of these methods but they appear to offer the least risk in the more serious cases.

The hernia can be repaired intra-abdominally as has been frequently reported the sac is inverted and the neck is ligated. Some patients so treated have remained well over a period of years without recurrence. However the usual anatomical repair either at the time of operation or when the patient is in better condition is the preferred method.

In the cases collected by Treves there was a mortality of 62.3 per cent in those not operated upon. With rare exception all those recovering spontaneously developed persistent fecal fistulae. The operative mortality in his group was 56 per cent—4 patients of the operative group having persistent fecal fistulae. In Bissell's review of the 20 years preceding 1920 the operative mortality was approximately 25 per cent and none of this recent group had a persistent fecal fistula. The mortality is much higher in femoral hernia since gangrene is apt to occur more rapidly due to the fact that the neck of the sac is smaller and constriction is more apt to occur.

SUMMARY

Two patients with Richter's hernia are reported. Both occurred in the femoral region and in each instance the terminal ileum was involved. In one the appendix was incarcerated in the femoral sac beneath the engaged intestine.

The majority of these patients do not have complete intestinal obstruction so that strangulation may not be evident. Diagnosis is rarely made before operation. In all cases with symptoms suggestive of partial intestinal obstruction it is important to examine all possible hernia sites.

It seems reasonable to expect a lowering of mortality following operation with the early recognition of partial intestinal obstruction together with a knowledge of this form of hernia.

A MUSCLE PEDICLE REPAIR OF DEFECTS IN THE PARIETAL PLEURA¹

JOSEPH B. STENBUCK, M.D., F.A.C.S., New York
Associate Surgeon, Harlem Hospital

ON the division of thoracic surgery of Harlem Hospital penetrating wounds of the chest due mainly to knives and bullets are of frequent occurrence. We are therefore, frequently presented with the problem of closing a defect in the parietal pleura rapidly and securely. The defect may be due to the knife of the assailant or to the exploratory incision of the surgeon. It was for the purpose of lessening the time of operation and anesthesia (and therefore the operative shock) and producing an air tight closure of the thoracic wall that the operation to be described was designed.

Intercostal pleural defects may be repaired by means of pericostal sutures (as advised by Lillenthal) in which case sutures are passed over the rib above the defect through the pleural cavity and under the rib below the defect, and then tied in such a manner as to bring the two ribs together and obliterate the defect. This is an excellent method in cases of incisions made in so-called 'interval thoracic explorations,' but it has seldom been applicable in our experience to penetrating wounds because of certain anatomical factors.

Penetrating wounds, particularly stab wounds, may make irregular defects in the chest wall by fracturing the lower thinner border of the rib thus leaving a rough edge devoid of intercostal muscle which prevents air tight closure even when the ribs are brought tightly together.

Occasionally a small section of rib or cartilage must be resected in order to reach and ligate a bleeding intercostal or internal mammary vessel which otherwise could not be clamped. This makes an irregular defect.

Stab wounds in the chest occur in our experience almost uniformly in one of these topographical groups:

1. *On the anterior chest wall* within a short distance of the sternum and frequently through the costal cartilages. The victim receives the blow unexpectedly usually on the left side, from a right handed assailant.

2. *Near the lower costal margin* in the anterior axillary region. This blow is received as the victim turns aside and raises his arm to protect himself.

3. *In the back* between the border of the scapula and the spinal column. This blow is generally

produced as the victim attempts to escape or to protect instinctively the more vital anterior portion of his body.

An anatomical consideration of these regions will show that near the sternum, at the costal margin anteriorly and near the spinal column, the ends of the ribs are attached at fixed points and at fixed distances. Because of this fixation attempts at bringing the ribs together by pericostal sutures have been unsuccessful frequently in our experience.

Attempts have been commonly unsuccessful, too, in suturing muscle over a defect in parietal pleura. Moreover in the large triangular area bounded by the borders of the pectoralis major and latissimus dorsi muscles anteriorly and posteriorly, and by the costal margin below there is little muscle with which to cover a defect. In addition, the intercostal muscles near the sternum contain fewer muscle fibers than the axillary portion or the posterior portion.

In a few cases we have obliterated a defect of parietal pleura by suturing the diaphragm to the parietal pleura thus plugging the defect and walling off the general pleural cavity. This gives a picture exactly like that found in the first stage of the operation for approaching a subphrenic abscess in which the diaphragm is attached to the parietal pleura. This method has been highly satisfactory in the few cases in which it was used but it has limited use.

In our earlier experience closure of a pleural defect was tedious patchwork which we have been able to obviate by the use of a muscle pedicle, the free end of which is placed into the pleural cavity, (not on the aperture) and held in place by suturing it to the structures at the edge of the aperture.

THE OPERATIVE PROCEDURE

The pectoralis major or the latissimus dorsi muscle was employed in all cases except one. (In that case the pectoralis minor was used because the pectoralis major was lacerated and crushed by the assailant who wielded a scissors with the blades held an inch or two apart. The pectoralis minor was severed at its origin and brought down.) The thickness of the muscle flap should be made slightly larger than the pleural defect so that it will fit snugly into it. The length should be suf-

Fig. 1. The muscle pedicle *a* severed and lifted from its bed, ready to be inserted into the orifice *b* into the pleural cavity. Note that the length of muscle required is longer than apparently necessary to reach the pleural orifice. This is made so because the pedicle contracts considerably after it is severed.

Fig. 2. A. The pedicle has been inserted into the orifice. The bed from which the pedicle was taken may be covered by suturing the border of the pectoralis muscle above to the border below. There is no disadvantage, however, in leaving it open. The pedicle is held in place by sutures to the adjacent muscle, fascia, or perosteum. While the pectoralis major is indicated in these diagrams, the latissimus dorsi may be used in a similar manner. In our experience these two muscles alone were adequate, when made into a pedicle, to reach all pleural defects.

B. This is a cross section of the thoracic wall after the pedicle has been inserted into the defect in the wall. Note the tongue of muscle is well inside the pleural cavity. In one of the cases in which the operation was performed, there was a complication of an infected hemothorax. Drainage was established at another portion of the chest wall and when the pleural cavity was clean, an investigation was made through the drainage wound of the pleural portion of the muscle pedicle and no abnormality was seen, as granulation tissue covered the area in the same manner in which it covered the remainder of the parietal pleura.

ficient to allow the flap to drop into the pleural cavity for a distance of approximately one inch. No harm will come from too long a flap extending into the pleural cavity while too short a flap will have a tendency to retract from it. The flap should be cut in such a manner that the base of the pedicle is near the pleural defect and the point of severance of the muscle is distal to it. When we began this method of closure we found that in spite of measurement of the length of muscle apparently necessary for the pedicle flap we were making too short a flap. This was due to the fact that it contracted after section of the muscle. We overcame this difficulty by increasing the length of the flap so that it was about one and one half times the length apparently necessary. In this way we produced a muscle flap which fitted snugly and without tension. It is of extraordinary interest to see how such a flap is actually sucked into the pleural cavity when placed at the orifice of the pleural defect, and how it will be held in place even without suture in ordinary respiration, to be dislodged only in violent respiration or sharp coughing. It serves as a perfect stopper but should be held in place with a few interrupted sutures or better a continuous suture attached to adjacent muscle or perosteum. It might also be held *in situ* by the pressure of gauze packing.

The advantages are not merely speed and efficiency in immediate closure. The same result might be obtained by tight packing with iodo-

formized gauze. Muscle, however ordinarily withstands infection well except in cases in which it is crushed with great force as in compound fractures and severe lacerations. Therefore, while we may depend upon gauze or fascia as temporary stoppers, they may become useless in a short time because of infection and subsequent sucking wounds. One should not hesitate to sacrifice as much pectoralis or latissimus dorsi muscle as necessary to plug the pleural orifice, since the loss of function is not serious. This may be seen frequently in cases of radical amputation of the breast in which the pectoral muscles are removed *in toto*.

We have employed this procedure in 14 cases with failure in only 1. In this instance we used two flaps in the same defect and one of these flaps was macerated muscle. The failure was partial in that the flaps were competent until the fifteenth postoperative day when they separated. By that time however the mediastinum had become

fixed so that no distress was experienced by the resultant pleural fistula.

The procedure is recommended not only for pleural defects due to penetrating wounds but also for defects following resections involving the parietal pleura. Our experience, however, has been limited to the former type of case.

CORRESPONDENCE

CONGENITAL CYSTIC DISEASE OF THE LUNG

To the Editor: Please permit me to make a belated correction to an article which appeared in *SURGERY, GYNECOLOGY AND OBSTETRICS* for March 1931. This article, entitled *Congenital Cystic Disease of the Lung*, by Doctor Eloesser in the discussion of the number of reported cases of congenital cysts of the lung stated that there had been but 4 American cases, 2 of R. T. Miller, a description of an anatomical specimen by Pappenheimer of New York and 1 of my own.

In 1925 I published (*Bulletin of the Johns Hopkins Hospital*, vol. xxvii, p. 340) what I thought was the first American case of this condition and reviewed all previous cases that I could find in the literature. Since then I have discovered that Doctor Pappenheimer of New York had published a case in 1912. My reason for overlooking his case was probably due to the fact that it was not published in a medical journal of wide circulation. The other

cases mentioned by Doctor Floesser have been published since the publication of my case in 1925.

Doctor Miller reported only 1 case of congenital cystic lung. The second case he referred to was my own as a careful reading of his article will show since he publishes one of my own illustrations illustrating this case. His failure to refer to my article was due, I am sure, to the fact that both his article and mine were in process of preparation at the same time, mine having been published only 2 months before his.

A. R. KOONTZ.

JOHN B. MURPHY

Material is being collected for an authorized biography of Dr. John B. Murphy. If any reader of this *JOURNAL* has in his possession letters from Dr. Murphy knowledge of facts concerning his life or any other data, it would be appreciated if they were sent to the Editors. All material will be returned promptly and the source credited.

MARCH, 1933

THE REVOLUTION IN THE MANAGEMENT OF PHTHISIS

AS recently as 1925 surgical measures were being used for pulmonary tuberculosis by only a few physicians. Today these measures dominate the active treatment of the disease in the leading tuberculosis centers. Although this change has not been brought about by any unique dramatic discovery it is nevertheless an event of prime interest to the medical world because phthisis is still the leading cause of death between the ages of fifteen and forty five years.

An era of hope about the curability of progressive cavernous phthisis has succeeded decades of resignation or false optimism on the part of both physicians and patients during the years when the sanatorium regimen was their only weapon. Nevertheless the sanatorium unaided by surgery has cured many thousands of patients and as long as tuberculosis exists it will probably remain as the indispensable foundation upon which any active treatment will be built. But the fact must be faced that its greatest independent success is for those patients whose lesions are

not extensive and chronic and whose cavities, if present at all, are relatively small and soft walled. The great majority of sanatorium patients belong to the far advanced group in which the death rate without surgery is shockingly high.

The pioneers repeatedly demonstrated during a period of many years that surgery (which term for convenience is intended to include induced pneumothorax) offers to a large group of patients with advanced tuberculosis hope in the face of impending disaster and that these patients contrary to general teaching withstand expertly performed major thoracic operations remarkably well. Yet the medical profession as a whole refused until relatively recently to accept surgery. This has been due in part to the profession's traditional resistance to any change from therapeutic orthodoxy. This wariness has been accentuated in the case of tuberculosis because of the utter failure of many highly praised cures. Other contributory factors have been the great emphasis that has long been placed upon the non therapeutic aspects of laboratory research in tuberculosis, the many ill advised or improperly performed operations that untrained surgeons presented as examples of the surgery of pulmonary tuberculosis and the fact that until recently relatively few competent thoracic surgeons were available.

What resistance to surgery remains is almost wholly passive and is based upon non-familiarity with the subject or upon apathy. It is especially to be regretted that many of our largest state and federal sanatoria, which should have taken the lead in offering life-

saving surgery to their wards have even yet taken no adequate steps to do so

In a large sanatorium in this country, 66.3 per cent of whose patients have far advanced and 28.3 per cent moderately advanced tuberculosis some form of surgery has been used for 77.1 per cent of all patients admitted with the adult type of pulmonary tuberculosis during a recent eighteen month period. It is interesting that the patients themselves who are notably close observers of the results of the different operations used for their fellow patients, rarely reject any recommendation for surgery.

The many operations now available afford great flexibility in the choice of the procedure or combination and sequence of procedures that is most likely both to heal the lesion and to conserve maximum function. Certain patients for whom temporary or permanent phrenic nerve interruption and pneumothorax have been tried and failed present suitable indications for closed or open intrapleural pneumolysis, oleothorax, extrapleural pneumolysis with paraffin, pectoral muscle gauze, or rubber bag filling, scalenectomy, temporary or permanent intercostal nerve interruption, partial thoracoplasty, or some combination of these operations and may thereby be saved from the necessity of having the more dangerous total thoracoplasty.

Total thoracoplasty is, however, indispensable for selected cases in which much of one lung is actually destroyed. A restricted thoracoplasty often fails to close a cavity and a persisting partially open cavity remains a lesion of grave ultimate significance no matter what gratifying general improvement the patient may have made after operation. A restricted thoracoplasty which fails to close the cavity is a radical and not a conservative measure because a patient who is subjected to the risks that are common to any thoracoplas-

ty should receive the full benefits to which those risks entitle him. Fortunately, it has been found that a very extensive thoracoplasty in three, four or more stages, is as safe, and certainly much more effective, than the restricted one or two stage thoracoplasty that is still too often used. There are two clinics, which happen to be known to the writer in which, during the past eighteen months among a total of one hundred and eleven consecutive patients, representing two hundred and ninety nine major operations, there have been only two deaths during the first post operative month and six deaths thereafter. These patients do not represent a group in which only those with ideal indications for thoracoplasty were included and with doubtful indications excluded, among them were many patients with a poor operative prognosis but a hopeless one without operation.

The modern sequence of measures used in the management of pure tuberculous and mixed tuberculous and pyogenic empyema has vastly improved the results and has dissipated much of the former utter pessimism about the curability of this dreaded disease.

The balanced judgment of the combined medical and surgical points of view is necessary to control undue enthusiasm or timidity and for the selection of the best possible operation for the individual patient. A surgeon's experience with phthisis may not have been sufficiently broad to entitle him to express himself with authority as to what operation is best for the particular patient. On the other hand the mere fact that an internist may be a specialist in tuberculosis and thoroughly familiar with the history of his patient does not necessarily qualify him to pass expert judgment in matters of surgical therapy, if his experience with it has been limited.

The subject as a whole is complex and the margin between safety and danger and be

tween cure and mere improvement is narrow. In many countries an increasing number of medically minded surgeons and occasionally surgically minded internists are apprenticing themselves to active thoracic surgical clinics in preparation for the competent practice of thoracic surgery as a specialty. The medical profession has finally accepted the contributions of surgery as the most hopeful and successful advance that has been made in the treatment of pulmonary tuberculosis since the sanatorium idea was introduced fifty years ago.

JOHN ALEXANDER.

PEPTIC ULCER

CURES or treatments, of peptic ulcer have been numerous usually introduced with enthusiasm that soon subsides to be followed by various modifications and gradually pass into disuse to be repeated with another method.

One explanation of this phenomenon may be found in a study of the natural history of untreated cases which shows peptic ulcer to be a chronic disease with the ulcer as a striking local manifestation characterized by cycles of recurrences and remissions but with a natural tendency toward repair.

Treatment to be rational should be based upon etiology. The possibility of hydrochloric acid because of its constant presence acting as an important etiological factor has been recognized by many notably and recently by Matthews and Dragstedt. This relationship may be emphasized by a consideration of ileal ulcers adjacent to Meckel's diverticula that contain gastric mucosa.

Treatment striving to neutralize hydrochloric acid after its secretion has not been very successful and therefore an attempt at minimizing its secretion has been offered as an improvement. Proper treatment may well

be multiple with efforts being exerted in four directions namely

- 1 Co-operation of the patient (much has been said about the advisability of co-operation between the internist radiologist, and surgeon but of more importance is a change in the patient's attitude from that of a miracle searcher to that of a co-operator with the physician). The methods of education so successful in the management of diabetes might well be imitated in peptic ulcer.

- 2 Social and economic readjustments will usually be necessary preliminaries in securing the essential factor of rest (physical and psychic).

- 3 Medical or non-operative management includes antispasmodics, alkalis or antacids emollients and various miscellaneous measures that are often followed by symptomatic relief which may with difficulty be differentiated from the remissions which characterize the disease. In this connection the statement of Ryle may be repeated. We should be interested in peptic ulcer the disease and not peptic ulcer the lesion.

Diets are numerous frequently conflict in theory but are followed by a strikingly similar percentage of favorable results. Dietotherapy should aim not only to neutralize hydrochloric acid already secreted but should also aim to diminish its secretion and should precede and follow all surgical measures.

It is not possible as yet to describe in detail the mechanism of hydrochloric secretion. All of the mechanisms suggested depend upon selective membrane properties. There can be no doubt that the blood base chlorides are the raw materials for gastric hydrochloric acid and that a mechanism exists for converting these simple chlorides into hydrochloric acid which diffuses outward into the stomach (free or combined) while the basic component diffuses in the opposite di-

rection into the blood stream. The phenomenon of 'alkaline tide' is as authentic as is the presence of hydrochloric acid in gastric juice.

If this quotation from Bradley is granted then a salt free or salt low, diet is plainly indicated in an effort to decrease the reserve and in turn the available chloride that might unite with hydrogen to form hydrochloric acid. Such a diet has been utilized in cardiovascular renal diseases, epilepsy, tuberculosis and in peptic ulcer by Krantz and Silver.

4. Surgical. The indications for operative measures may at the present time be outlined as follows: with acute ulcer perforation calls for surgery; hemorrhage for non-operative management with chronic ulcer non-operative measures may be given a number of trials in duodenal ulcer but because of malignant potentialities prompt surgical measures may be advisable in gastric ulcer.

The usual operative procedures such as resection (which removes the effect and allows the cause to remain) and pyloroplastics or gastro-enterostomies (which destroy or nullify the pyloric mechanism) are frequently followed by return of symptoms and sometimes secondary ulcer.

Indirect methods such as vagotomy, adrenal denervation, partial devascularization, radiotherapy, physiotherapy, psychotherapy, protein shock and many other types of therapy have been recommended.

The physiological fact that the fundus secretes acid and the antrum alkali has not until recently been applied in treatment. With repeated operations for recurrent ulcers one finds more satisfactory results as more

and more of the fundus has been removed and it seems more rational to remove the cause (the acid) than to remove the effect (the ulcer) and allow the cause to remain.

A direct method of diminishing the secretion of hydrochloric acid by minimizing the area capable of such function (the fundus) as a primary and not a second or third operation, and especially applicable in cases of jejunal ulcer has been carried out by Connell and is now on clinical trial.

By so doing the lesser curvature the *Magenstrasse* an important factor in motility is retained, and the pylorus with its antro-pyloro-duodeno-neuromuscular mechanism so essential in local neutralization and in maintaining general acid base equilibrium is not sacrificed.

Fundusectomy is offered as a compromise between gastro-enterostomy which by some is considered too conservative and gastrectomy which by many is considered too radical. It also complies with the very fair requirement of Balfour that 'It should not interfere with future surgical treatment, should ulcer develop subsequently.

EARLY AMERICAN MEDICAL SCHOOLS

ALBANY MEDICAL COLLEGE MEDICAL DEPARTMENT OF UNION UNIVERSITY

ITS FOUNDING AND DEVELOPMENT

A HAZEL CURRY, M.D. ALBANY, NEW YORK

Assistant Professor of Bacteriology, Albany Medical College

THE Albany Medical College owes its existence to the eighteen years of ceaseless perseverance of Dr. Alden March. A lecture delivered by Dr. March, January 11, 1830 "On the Expediency of Establishing a Medical College and Hospital in the City of Albany" reveals the fact that he had conducted private courses of medical instruction since November 1821. The new college was organized in 1838 and formally opened January 1, 1839. It was incorporated by the New York State Legislature, February 16 and graduated its first class on April 24, of the same year the thirteen members having completed their course in four months. Today this

institution is the second oldest surviving medical college in the state as only one of the three which antedated its inception is now in existence.

Although Dr. March had hoped for a "practical school of medicine, such as is afforded by a well regulated hospital" (a) the Albany Hospital was not opened until 1851. The objects of the corporation set down in the by laws at that time read as follows:

"1. To provide philanthropy by the establishment within the city of a hospital and dispensaries to furnish medical and surgical aid and trained nursing to sick and injured persons.

2. To promote medical education by maintain-

The original doorway as it appears in the new building.

ing a school of instruction in the science and art of medical and surgical nursing and by offering opportunity for clinical and laboratory instruction to medical students." (1)

Despite the lack of hospital facilities in the first years of the medical school, practicability as the basic principle of Dr. March's pedagogy was evidenced in his clinical presentations. "On the first Saturday of the term, Dr. March inaugurated his surgical clinics, held in the college and at which he presented a large number of cases requiring operation or treatment and this new feature in medical education which he introduced soon came to be generally adopted by medical schools throughout the country." (6)

The first president of the faculty was Dr. March who served in this capacity from 1839 to his death in 1869 a period of thirty years. This remarkable physician and surgeon thus gave nearly fifty years of his life to the founding and development of the Albany Medical College and Albany Hospital. His successors have been Dr. James McNaughton until his death in 1874, Dr. James Armsby until his death in 1875. At this time the title of president of the faculty was changed to that of dean. Dr. Thomas Hun served as dean until his death in 1896. Dr. Albert Vander Veer to 1904, Dr. Samuel B. Ward to 1914, Dr. Willis Tucker to 1915 and since then Dr. Thomas Ordway under whose administration the new Albany

Medical College has been built and the Albany Hospital reconstructed.

In 1873 the Albany Medical College became a unit of Union College retaining however, its own name, its own trustees, and its hitherto existing corporate rights. In 1915 the college was reorganized for teaching on a university basis" (5). In 1927 the Albany Medical College and Albany Hospital became legally united by the formation of a Joint Administrative Board to function as a hospital medical college, thereby promoting medical education and affording more effective treatment of patients.

The indefatigable labor of Dr. March a century ago to establish this institution is a tradition of patience, research and careful planning which has been followed faithfully throughout the ensuing years. This policy has brought to the school recognition for reliability and dependability. The constantly increasing service of the Albany Medical College is evidenced in one of its latest developments—its Regional Extension Department. By means of this regional work it maintains contacts with physicians throughout a wide rural area affording them opportunities for acquiring knowledge of the newer developments in medicine and strives to make medical service accessible to all communities. In aiding graduates to keep abreast of the new medical and surgical achievements as well as in the teaching of under

Aeroplane view of Albany Medical College buildings.

graduates, the Albany Medical College holds to the ideals of the founder. "The value of our pursuits can be estimated only by the value of life itself and of that which alone endears it to its possessor—health. The enlightened and judicious practitioner of medicine is justly ranked among the benefactors of mankind. In proportion as his time and talents are employed in acquiring an accurate and extended knowledge of his profession in the same proportion will he become useful to his fellow citizens, and be entitled to their approbation and support. He should not be devoted to the mere sordid accumulation of wealth. A more noble, generous, and humane motive should hold the first place in his sentiments and actions. Prevent and relieve human misery should be his motto engraved in indelible characters on the tablet of his heart." (3)

BUILDING OF ALBANY MEDICAL COLLEGE

During its existence of more than ninety years, the Albany Medical College has had two homes, its present one on University Heights, New Scotland Avenue and its first one on Eagle Street, between Jay and Lancaster Streets. The latter was originally the Lancaster School building which was completed in 1817 having been designed by Philip Hooker, a noted architect of his time. With the passing of the Lancasterian monitorial system of teaching, the Common Council of the City of Albany voted, March 28, 1836 to close the doors of the school. Dr. March ever alert, saw the opportunity to secure this place for his proposed medical college and applied to the Common Council for the building for such purpose in the event of a charter being granted by the legislature. (4) Finally April 16, 1838, the Common Council voted to lease the property to the trustees of the Medical College for five years

rent free, the petitioners having agreed to repair the already dilapidated building and to surrender it in good condition at the end of the term specified.

The new building, modern and capacious, is in direct continuity with the Albany Hospital and in close proximity to the School of Pharmacy, the Albany Law School and the Dudley Observatory, all units of Union University, the New York State Laboratory and the Bender Laboratory. In addition to its own library the medical college has access, through its courier system, to the reference books in the New York State Medical Library, the nucleus of which was formed by books given to the state by the college in 1890.

In the new building the original doorway still stands, the white marble threshold, worn by years of service, has echoed and re-echoed the firm, determined footstep of the founder as he entered to open the Albany Medical College on the second day of January, 1839. The two colonial fireplaces, one in the library and the other in the trustees room memorialize years of progress which have made possible the Albany Medical College and Albany Hospital of today.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE human breast an organ with a peculiar anatomical construction, is during a considerable period of life subjected to various stimuli. It responds to these stimuli be they physiological or otherwise in a manner which is unique and at times mysterious. The superficial location of the breast makes for relatively prompt recognition of anatomical and functional abnormalities. Groups of these abnormalities whether physiological or pathological, have been recognized and described however there is in the mind of most medical men a sense of confusion relative to these conditions—one need mention only the term "chronic mastitis" and place it in the category of rheumatism and like terms. An analysis of the situation immediately suggests the reason for this confusion, namely the lack of concerted study for a sufficient period of time to justify an opinion.

The work of Cheate and Cutler is therefore a most welcome and satisfying contribution to the subject of breast pathology. Their conclusions are the result of some thirty five years of continuous clinical and microscopical study of the breast based upon a definitely established theory and verified by numerous serial sections of the entire breast. For the first time there is established a principle of breast pathology which is clear and concise and which is proved by ample concrete evidence.

The authors divide epithelial growths into two types of desquamative hyperplasia—mazoplasia and the cystiphorous—and neoplasia. The term chronic mastitis and chronic cystic mastitis as they appear in the literature include under their description states of the breast which are more physiological than pathological and also states which are distinctly pathological (cysts and papillomata). These states differ from each other in their etiology, prognosis and treatment so that it is of importance to separate them. The authors have isolated that condition which appears to be more physiological than pathological and describe it under the term of mazoplasia.

Mazoplasia is that condition in which there is a type of desquamation of the epithelial cells in the terminal ducts and their acini with hyperplasia of the pericanalicular and periacinous connective tissue and often with new formation of ducts and acini. The shed epithellum which consists of cells which are irregular stain poorly and are in a state of de-

generation may distend the ducts and acini giving rise to diffuse pain and if the breast is not too fet a generalized fine nodularity which can be felt upon palpation. Cysts do not belong to this state but are associated with an entirely separate and distinct pathological process. In the normal breasts of all women who have borne children mazoplasia is almost universally present in some degree until the menopause and the only pathological state that can be directly traced to it is the formation of fibroadenomata.

Cystiphorous desquamative epithelial hyperplasia is that type of hyperplasia which ends in the formation of cysts. It is entirely different in its biology and morphological appearances to that of mazoplasia although the two may coexist. In mazoplasia the type of epithellum remains stable and forms neither cysts nor papillomata moreover the acini never coalesce. In the cystiphorous type the epithelial hyperplasia may undergo a radical change into epithelial neoplasia the change being traceable morphologically in all stages of transformation. About 20 per cent of all cases of carcinoma of the breast can be definitely traced to begin within the lesions of the cystiphorous state the supervention occurring in the late fourth and early fifth decade and requires a period of about thirty years to culminate. The authors have shown that the process may become arrested in the decade of cyst production. In others it may stop at the decade of benign neoplasia (papilloma) from which state it may pass into the decade of malignant neoplasia (carcinoma). This fact makes the lesion one of great menace and of immense portent.

The authors believe that papillomata are much more common than is generally supposed. By a study of whole microscopical sections of the breast they have been able to demonstrate their presence when not in the least suspected moreover they have shown that papillomata are generally multiple, as many as 150 tumors having been counted in one microscopical section of the whole gland.

In a discussion of neoplasia there is an interesting description of tumor formation and the association of carcinoma with pre-existing epithelial neoplasia. The authors stress the importance of staining the elastica in studying and interpreting morphological appearances. The problems encountered in carcinoma Paget's disease of the nipple and benign tumors are expounded in a meticulous manner. There is included a chapter on radiation treatment of carcinoma of the breast. The authors conclude that

TUMORS OF THE BREAST. THEIR PATHOLOGY, SYMPTOMS, DIAGNOSIS, AND TREATMENT. By Sir G. Leslie Cheate, K.C.B. C.V.D. F.R.C.S., and Max Cutler B.Sc. M.D. Philadelphia and Montreal. J. B. Lippincott Company. 95.

since the reported percentage of cures of mammary carcinomas by operation alone vary within such wide limits, it can hardly be expected that the value of radiation can be determined by comparative means. They report some statistical studies but state that several years must elapse before sufficient and accurate data are available. The authors favor the use of pre-operative radiation in selected cases and postoperative radiation in moderate repeated doses.

This work which is claimed by 18 colored plates and 468 illustrations all original is indeed a master piece. It represents the untiring efforts of many years of progressive and thoughtful study based upon a workable hypothesis relative to tumor formation in the breast.

J. A. WOLFE.

ATLASES of obstetric roentgenology have been wanted ever since the earliest days of the use of the X rays for one of the first applications of X ray diagnostic methods was to the female pelvis and to the fetus. But because of mechanical and technical difficulties only within recent years has it been within the power of the radiologist to produce roentgenograms of the fetus *in vivo* matrix which from the photographic standpoint could be utilized for publication purposes. Ordinarily the extremely contrasty roentgen films, although rich in detail of both maternal and fetal parts and serving excellently for diagnostic purposes, could not be reproduced photographically and on the printed page without great loss of detail. These difficulties still exist to a certain extent but by improvements in the apparatus and technique of roentgenology and by bringing to the obstetrical clinic the artificers of the professional photographer in retouching negatives, it has been possible for Liepmann and Danclous to publish their beautifully printed and illustrated atlas.

The authors discuss the development of obstetrical roentgenology, the normal position of the fetus, the various changes which may occur and the forces and factors which may bring them about, varieties of pelvic deformities, spontaneous changes in the position of the fetus, a long series of observations on the mechanism of birth, a discussion of the unusual and pathological positions of the fetus, pelvic and fetal malformation, deformities and monstrosities, intra uterine fetal death, and other pertinent questions relating to obstetrics in which the roentgenograms throw light or assist in illustrating. Most of the roentgenograms are accompanied by line drawings which clarify the interpretations. The volume is a valuable contribution to roentgenology and to obstetrics and will undoubtedly be regarded as a classic.

JAMES T. CARR.

IN a compact volume Jacobson has succeeded in making available to medical students and practi-

tioners, a comprehensive, concise and readable discussion of the subject of clinical mycology.

There are ten chapters, entire chapters being devoted to dermatomycosis, moniliasis, madaromyces, sporotrichosis, blastomycosis, actinomycosis, coccidioides, torulosis, and aspergilliosis. The history of each disease is first discussed, then the etiology, mycology, clinical manifestations, pathology, diagnosis, and finally the treatment. Each subject is very thoroughly covered, and there is a complete bibliography with each chapter.

The illustrations are for the most part very good, the print and paper excellent. The book reads well, and should prove to be of great service to the dermatologist, internist, and general practitioner.

EDWARD A. OLIVER.

THIS work on the individuality of the blood by Professor Lattes, first appeared in Italian in 1923, in German 1925, in French 1929, and now in English. It has been revised and enlarged until at present it consists of 413 pages of general review of the subject and citation of the work of leading students in the field. The author crystallizes the various data, opinions, and methods into a very readable volume. The bibliography of the book is extensive (91 pages).

Attention is concentrated on those constitutional peculiarities of the blood which enable us to distinguish between individuals of the same species. This is what is meant by "individuality of the blood with which this book is alone concerned. These individual characteristics have not been demonstrated by morphology or chemistry but almost entirely by serology.

The hereditability of the blood characteristics caused v. Dugern and Hirschfeld to state that the bio-chemical structures of A and B serotypes never make their appearance in the offspring unless they are present in one or both of the parents. "If parents contain 'peculiar structure,' it will be found as a rule in their children. The transmission of the blood groups takes place according to Mendel's law and the so-called agglutinable properties A and B behave as dominants, but they are affected by a allelomorphous character, one being derived from each parent, the combination of which give rise to 6 genotypical blood groups. These findings bear out Mendel's laws of heredity in man. Much data are presented on the individuality of the blood as an ethno-anthropological fact. It is clear that the study of the blood groups made go far in solving the origin of races of men. These same principles are becoming well established in forensic medicine to establish the parents of children. Thirty-four pages are given to technique of

using the points discussed in this book. One section of the volume is given to blood transfusions.

M. H. BARKER.

A BOOK¹ which is just what the name implies—a clinical study of endocrinology has been written by Mazer and Goldstein who are essentially clinicians. The presentation therefore follows the natural clinical sequence of events. The functional phases are taken up in their normal order—puberty, menstruation, pregnancy, lactation, and the menopause. The latent and newest thoughts in endocrinology are fully expressed and a rather considerable portion of this monograph is devoted to therapy. It is this portion of the work if any, which one feels tempted to criticize adversely. Endocrinology is not at present a completed study and endocrine therapy is still in its infancy. Much careful and intensive work must be done before final statements may be made. The authors show a tendency to be dogmatic. The administration of anterior pituitary sex hormone is almost a specific in the treatment of functional uterine bleeding of puberty and maturity. This phase of gynecological practice would be greatly simplified if such were the case.

The monograph is well illustrated. It ends with a bibliography of 649 articles on the subject and is most worth while as a handy and useable reference work on endocrinology in the female gathering together as it does the voluminous literature on the subject. In addition it presents the personal contributions of the authors. These are considerable and lend to the work a most intimate and attractive style. It is a monograph well worth the reading.

RALPH A. REIS.

FOR various reasons the book² by Doll and his collaborators on *Mental Deficiency due to Injuries* is valuable. To some extent it supplies information of unquestioned validity. It emphasizes the challenge already repeatedly made by others that obstetricians should make persistent efforts to discover methods by which the incidence of birth injury can be reduced.

The most important contribution, however, is the evidence that careful, resourceful study of individuals suffering from cerebral palsy by psychologists and orthopedists reveal possibilities unsuspected by less thorough methods. Obviously the attitude that among birth injured subjects we have a kind of natural experiment in neuropsychology for studying the relation of behavior to cerebral integrity is both correct and stimulating. Dr. Doll and his co-workers properly and fortunately regard this volume as a preliminary report. As such it has great value and interest.

BRONSON CROTHERS.

CLINICAL ENDOCRINOLOGY OF THE FEMALE. By Charles Mazer, M.D., F.A.C.S., and Leopold Goldstein, M.D. Philadelphia and London: W. B. Saunders Company, 1931.

MENTAL DEFICIENCY DUE TO BIRTH INJURIES. By Edgar A. Doll, Ph.D., Whitrop M. Phelps, M.D., and Ruth Taylor Melcher, M.A. New York: The Macmillan Company, 1932.

AS described in the title Bertwistle's *Atlas*³ a collection of 767 reproductions of positive prints from roentgenograms including examples of most of the pathological lesions ordinarily encountered. Each roentgenogram is accompanied by a few lines of text and sometimes by a descriptive outline drawing. Often the text seems inadequate to illuminate the illustrations considering the author's intention to provide a working guide for the clinician who, without being specially concerned with the technical side, yet desires to know what radiology is capable of revealing to him. It is thought that the presentation of a number of plates with descriptions and clinical notes will enable him to realize which cases are suitable for this form of examination. An interesting chapter concerns milestones in roentgen diagnosis in which the author lists some of the outstanding innovations of each year in the development of radiology.

An unusual style is used for preparing the roentgenographic illustrations as silhouettes. The outline of the soft tissues is scratched in with a needle and a print made after which the silhouette is completed by filling in the background with India ink.

A serviceable atlas for the general practitioner and for the novice in radiology.

JAMES T. CASE.

THE monograph by Hartmann and Bérard discusses all phases of cancer of the tongue.⁴ Following an introductory chapter on the surgical anatomy of the tongue, the author presents an interesting historical review describing the development of our knowledge upon this subject. During the first period (1766) the tongue was looked upon as an object of religious respect because of the function of speech. During the second period (1850) attempts were made to overcome difficulties in operative technique. The third period (1880) was characterized by advances in the knowledge of pathological anatomy. It was during this period that simultaneous ligation of both lingual arteries was performed as treatment for cancer of the tongue. This procedure was followed by diminution in the size of the tumor. During the fourth period (1890) massive ligation was abandoned and leucoplakia was first recognized as a precancerous lesion (Trelat). The most important advance in technique consisted in hemostases effected by ligation of the lingual and external carotid arteries. The fifth period (1920) was marked by a recognition of the importance of block dissection of the neck, and it was during this period that the necessity for external removal of the cervical lymphatic glands secondary to cancer of the tongue was fully established. The sixth period is characterized by progress in the radiation treatment of this condition.

¹A DESCRIPTIVE ATLAS OF RADIOGRAPHS; AN AID TO MODERN CLINICAL METHODS. By A. P. Bertwistle, M.B. Ch.B. F.R.C.S. (Ed.) ed. ed. rev. and ed. St. Louis: The C.V. Mosby Company, 1932.

²ENDOCRINOLOGIE DU CANCER. Professeurs H. Hartmann et L. Bérard. Directeur: Dr. A. Chénier. Secrétaire: CANCER DE LA LANGUE. By Pierre Bérard. Paris: Gaston Doin & Co., 1932.

The author emphasizes the important rôle of syphilis in the development of cancer of the tongue. He correctly warns against the use of caustics such as chromic acid, silver nitrate and the thermogalvanic current in the treatment of leucoplakia, stating that these methods constitute the earliest manner of hastening the transformation of leucoplakia to carcinoma.

Chapters upon the gross anatomy, microscopical structure and the cause of the disease are complete, clear, precise and well illustrated.

Surgical excision is planned for the accessible lesion and for the removal of those less accessible.

Complete removal of the cervical lymphatic glands is advised when there is clinical evidence of disease. The technique of radium and X rays in the treatment of cancer of the tongue is described.

This treatise is a useful résumé of the subject clearly presented by a writer who evidently has had considerable experience with the disease. Some radiotherapists will differ with the author upon the wisdom of performing surgical excision of any carcinoma in the tongue regardless of its location. At the Carle Institute, for example, radium is the exclusive method even when the lesion involves the most accessible portions.

X RAY DIAGNOSIS OF ILEUS

THE VALUE OF ROENTGENOGRAMS IN SIMPLE AND STRANGULATED OBSTRUCTION AN EXPERIMENTAL STUDY¹

ALTON OCHSNER, M.D. F.A.C.S. NEW ORLEANS, LOUISIANA

IN acute intestinal obstruction as in the majority of surgical emergencies early diagnosis is of utmost importance. All else being equal the earlier the relief of an intestinal occlusion the better is the prognosis. Van Beuren has aptly stated: "The longer a patient with intestinal obstruction lives before operation the sooner he dies afterward." Any procedure therefore facilitating the early diagnosis of this condition which yearly claims so many lives should indeed be more extensively used.

The roentgen diagnosis of ileus has been used much more extensively in the past 5 years than previously, although its true value as a diagnostic procedure in ileus I am sure is not sufficiently appreciated. Obviously the administration of a contrast substance by mouth in suspected ileus is contra indicated and in such instances only plain roentgenograms of the abdomen should be obtained. The procedure first advocated by Schwarz in 1911 has been used extensively as evidenced by the numerous reports (Assmann, Case, Weil, Kloiber, Milhaud, Kolhfleisch, Meyer and Brams, Davis, Rahwin, Trémolières, Zadoc Kahn, Kwong, Weber, Milligan and Simon). The value of plain roentgenograms of the abdomen consists of visualization of accumulated gas or gas and fluid proximal to the point of obstruction. Normally gas is

present only in the stomach and in the large bowel and when found in the remaining portions of the intestine indicates the presence of either a mechanical or adynamic ileus. The relative values of roentgenograms obtained in such a way that the junction between gas above and fluid below might be visualized and those obtained to demonstrate an accumulation of gas alone have been discussed by many authorities. In order to visualize fluid levels i.e. the junction between the fluid below and the gas above it is necessary to obtain the roentgenogram by placing the patient the X ray plate and the tube in such positions that the rays will parallel the surfaces of the fluid contained within the intestine. This is accomplished by anteroposterior roentgenograms with the patient in the upright position or with the patient lying on one side or lateral roentgenograms with the patient in the supine position. Gas accumulation alone can be demonstrated on anteroposterior roentgenograms taken with the patient in the supine position. The advantage of the former is that the contrast between the gas and fluid gives a very definite picture. The advantage of the latter is that the usual technique of obtaining roentgenograms need not be varied. Assmann, Case, Weil, Davis, Meyer and Brams, Rahwin and Carter, Trémolières, Zadoc Kahn and Kwong, Weber, Milligan and Simon are

From the Department of Surgery, Tulane University School of Medicine, New Orleans.

TABLE I—JEJUNUM

Time in hours	Simple obstruction of jejunum					Strangulated obstruction of jejunum				
	Horizontal		Upright			Horizontal		Upright		
	Gas	Fluid	Gas	Fluid	Calce	Gas	Calce	Gas	Fluid	Calce
	13		3	5		27	3	27		13
4		37	2		3	25	44	20	14	24
5	90	90	10	15	27	28	30	24	21	30
7		11	4	20	27	71	61	73	30	30
	7	30	73	58	3	71	6	73	6	6
	21	30	71	60	27					
20	66	30	21	75	75					

of the opinion that visualization of the gas is sufficient and that the demonstration of fluid levels is unnecessary. On the other hand, Schwarz, Hoesslin, Wolf, Benaude and Guinéaux, Kloiber, Milhaud, Wynen, Kolb, Fleisch, Martens, Ochauer and Granger consider the demonstration of fluid levels in cases of ileus of sufficient importance to have roentgenograms made in such a way that they may be visualized.

Relatively little work has been done to determine the time at which X-ray evidence of ileus becomes positive. Kloiber believes that the accumulation of gas in the intestine can be demonstrated roentgenographically within 5½ hours after the beginning of obstruction. Case states that within 6 to 8 hours enough fluid and gas accumulate within the bowel proximal to the obstruction to be visualized by the roentgen rays. Wangenstein and Lynch found in animals that within 4 to 5 hours after complete occlusion gaseous distention proximal to the obstruction could be demonstrated roentgenographically. They believed that the accumulation of fluid proximal to the obstruction was less marked than that seen in humans unless the animal was given a saline infusion. They also found that there was less distention associated with strangulated than with simple obstructions. Subsequently, Goehl, Lynch, Borman and Wangenstein working with varying degrees of strangulation in isolated intestinal loops found that the gas accumulation as demonstrated roentgenologically did not occur as early as in simple obstruction. This latter

finding would seem to vitiate the value of roentgenograms as an early diagnostic procedure in ileus because it is in strangulated obstruction that early operative interference is especially indicated. It is a well known fact that the prognosis is much worse and the urgency for operative relief is much greater in the presence of strangulation than in simple obstruction. The value of plain roentgenograms of the abdomen in the early diagnosis of ileus however is exemplified by the results reported by Rabwin and Carter. The mortality rate during the 8 months that roentgenological diagnoses of ileus were made was 23 per cent as compared with 53 per cent, 37 per cent and 40 per cent, respectively for similar periods of time in 3 previous years.

In order to determine the relative values of roentgenograms taken in such a way that fluid levels might be demonstrated and those taken to visualize the presence of gas alone and in order to compare the roentgenographic findings in simple and strangulated ileus, the present investigation was undertaken. Twenty-three dogs were used in the experiment. In 7 obstructions were produced in the jejunum of which 3 were simple obstructions and 4 were strangulated obstructions. The simple obstructions were accomplished by tightly tying heavy binding tape around the gut. Strangulated obstructions were produced in a similar manner but in addition, the blood supply to the bowel proximal to the obstruction was interfered with by tying rubber bands around the individual vessels in the

The tape was not tied tight enough to produce necrosis

mesentery which ultimately resulted in gangrene. In 14 animals obstructions of the ileum were produced 9 of the simple and 5 of the strangulated varieties. In 2 animals a strangulated obstruction of the sigmoid was made. Plain roentgenograms of the abdomen were made at varying periods of time after the production of the obstruction, one with the animal in the upright position, and one with the animal in the horizontal position. The obtaining of roentgenograms with the animals in the upright and horizontal positions was facilitated by the use of an especially constructed animal board previously described by Ochsner and Gage. In all, 109 observations were made making a total of 218 roentgenograms, 109 obtained in the upright and 109 in the horizontal positions. In the reading of the plates the degree of gas or fluid accumulation was expressed as varying from + to + + + + + representing approximately 25 per cent and + + + + + representing gaseous distention of the intestine of the entire abdomen. Subsequently these were transferred into percentages and are used as a basis for the calculations that appear on the tables.¹

In simple obstructions of the jejunum (Table I) there were no X ray evidences of accumulation of gas or gas and fluid earlier than 3 hours after the production of the obstruction. However, roentgenograms taken 3 hours after the production of the obstruction were positive for gas accumulation (Fig 1) which increased in amount as the time interval increased. The accumulation of gas apparently occurred more rapidly than did the accumulation of fluid (Table I). As early as 4 hours after the obstruction there was evidence of accumulation of gas in the colon, i.e., distal to the point of obstruction the amount of which fluctuated considerably indicating that at times the gas would be evacuated. In general however it increased as the time interval increased.

In strangulated obstructions of the jejunum (Fig 11) as early as 1 hour after the production of the strangulated obstruction, there were accumulations of gas both in the bowel

Fig 1. Roentgenograms taken 4 hours after simple obstruction of the jejunum. A horizontal position is upright position. There is an accumulation of gas as shown in both roentgenograms but no evidence of fluid levels.

proximal to the obstruction and also in the colon, distal to the obstruction. There were no evidences of accumulations of fluid. The accumulations of gas increased rapidly in amount, much more rapidly than in the simple obstructions. As early as 3 hours after the production of the obstruction, there were evidences of fluid formation as could be demonstrated by fluid levels in the roentgenograms taken in the upright position. The gaseous distention of the colon distal to the obstruction also increased but less so than that in the bowel proximal to the obstruction (Fig 2). From these results, it is evident that in strangulated obstruction of the jejunum X ray evidence of the obstruction is positive as early as 1 hour after the production of the obstruction, whereas evidence of simple obstruction does not become positive until 3 hours after the obstruction. There also occurred distal to the obstruction principally in the colon, gaseous dilatation, which is probably reflex in origin. This was positive in the strangulated obstructions as early as 1 hour after the obstruction whereas in the simple obstructions, it did not occur until 4 hours after the obstruction. The roentgenographic signs not only occurred earlier but were more marked in the strangulated obstructions than in simple obstructions of the jejunum (Fig 3).

¹The percentages so obtained are obviously not absolute but only relative and are of value only when used in a comparative study.

Fig. 3. Roentgenograms of 3 hour obstructions of the jejunum. There is considerably more gas in the strangulated obstructed gut B than in that with simple obstruction A. In strangulated obstruction, B there is also considerable accumulation of gas in the colon, i.e., distal to the point of obstruction. Both roentgenograms were made with the animals in the horizontal positions.

In simple obstructions of the ileum (Table II) as early as 1 hour after the obstruction there were X ray evidences of accumulation of gas both proximal to the point of obstruction and in the colon, distal to the obstruction. The earliest evidences of fluid accumulation in simple obstructions were found 3 hours after the obstruction. The accumulation of both gas and fluid rapidly increased as

Fig. 4. Roentgenograms of strangulated obstruction of the jejunum taken 1 hour after the production of obstruction. The roentgenogram taken with the animal in the upright position A, shows gas accumulation and several fluid levels, as indicated by the arrows, whereas the roentgenogram of the animal taken in the horizontal position, B shows accumulation of gas above.

the time interval increased. The amount of gas accumulation in the colon fluctuated considerably, probably due to the fact that the gas distal to the obstruction was evacuated from time to time. In general however it also increased as the time interval increased. In strangulated obstructions of the ileum, there occurred as early as 1 hour after the production of the obstruction an accumulation of both gas and fluid proximal to the obstruction (Fig. 4). There were no evidences of gas in the colon. The gas and fluid accumulation rapidly increased as the time interval increased. It is evident that in the present investigation X ray evidence of ileus (accumulation of gas and fluid) was more marked in strangulated obstructions than in simple obstructions of the ileum (Figs. 5 and 6). There were also greater accumulations of gas and fluid in obstructions of the ileum than in similar obstructions of the jejunum (Figs. 7 and 11).

In only 2 animals were X ray observations made of strangulated obstructions of the sigmoid. In both as early as 1 hour after the production of the strangulated obstruction, there was considerable accumulation of gas and fluid (more of the former than the latter) proximal to the obstruction (Fig. 8). This

Fig. 5. Roentgenograms of 7 hour obstructions of the jejunum. There is considerably more gas accumulation in A (strangulated obstruction) than in B (simple obstruction). Both roentgenograms were made with the animals in the horizontal positions.

Fig 5 Roentgenograms of 5 hour obstructions of the ileum, both roentgenograms being taken in the upright position. A Strangulated obstruction of the ileum B simple obstruction of the ileum. There is a much greater accumulation of gas and fluid in the strangulated obstructed gut, A, than in the simple obstructed gut B. Fig. 7. Roentgenograms of 3 hour strangulated obstructions of the jejunum, A and ileum, B. There is a much greater accumulation of both gas and fluid (indicated by arrows in the obstruction of the ileum, B) than in the obstruction of the jejunum, A. Both roentgenograms were taken with the animal in the upright position.

Fig. 8. Roentgenograms of strangulated 3 hour obstructions of the sigmoid. There is an accumulation of gas in both roentgenograms. Fluid levels are visualized in the roentgenograms taken in the upright position, A. The roentgenogram taken in the horizontal position, B, shows the presence of gas even though the plate was taken only 1 hour after obstruction.

DEDUCTIONS FROM EXPERIMENTS

The value of roentgenography in the early diagnosis of ileus is exemplified by the present investigations. Simple obstructions of the ileum could be demonstrated roentgenologically as early as 1 hour after the onset of the obstruction by the accumulation of gas proximal to the obstruction. It is true that the amount of gas present in such simple obstructions within the first hour was relatively slight, but it was of sufficient quantity to be distinctly abnormal demonstrating that roentgenography as early as 1 hour after the obstruction could be of value clinically as a diagnostic procedure. More important however is the fact that in strangulated obstructions of the jejunum, ileum and sigmoid there were marked X-ray evidences of the obstruction as early as 1 hour after the obstruction, the accumulation of gas being more marked than that which was seen in the simple obstructions. In the obstructions of the jejunum and ileum, as early as 1 hour after the obstruction, there were also accumulations of fluid which were not present in simple obstructions of the jejunum. The fact that roentgenograms of the abdomen taken 1 hour after strangulated obstructions are positive is especially significant because as mentioned operative relief of strangulated obstruction

must be secured earlier and is more imperative than that of simple obstruction. A simple obstruction of the bowel in which there is no interference with the blood supply especially if the lower portion of the intestine is involved offers a relatively good prognosis. The urgency for operation is, however, materially increased as soon as there is an interference with the blood supply to the gut. These results do not coincide with those of Goehl, Lynch, Borman and Wangenstein who found less distention associated with strangulated obstructions than with simple obstructions. The discrepancy in the results may be due to the fact that Goehl *et al* worked with isolated intestinal loops whereas in the present investigation, the obstruction was produced by occluding the intestine and at the same time interfering with the blood supply in the mesentery, a factor which I feel is more apt to be encountered clinically except in cases of volvulus and certain cases of hernia. The greater accumulation of gas and fluid in strangulated than in simple obstructions appears paradoxical, but the explanation may be as follows. As a result of the interference with the blood and also the nerve supply to the gut, a local paresis and decreased ab-

Fig. 9. Roentgenograms of 4 hour strangulated obstructions of the sigmoid. There is considerable accumulation of gas in both plates, that taken in the upright position, B and that in the horizontal position, A. Fluid levels are visualized in the plate taken in the upright position, B.

Fig. 10. Roentgenograms comparing 4 hour strangulated obstructions of the sigmoid and ileum. In the strangulated obstruction of the sigmoid, A, there is a great deal more accumulation of gas than in the strangulated obstruction of the ileum, B. Both roentgenograms were taken in the horizontal positions.

sorbability of the bowel probably occurs. Gas and fluid from the normal intestine above the area of strangulation are forced by peristalsis into the dilated parietic portion of bowel where they remain because of obstruction and diminished absorbability of the intestine. This would explain the discrepancy between our results and those of Goehl *et al.*, who were unable to obtain early evidences of gaseous distention of strangulated isolated loops of intestine. Ultimately gaseous distention of strangulated intestine will occur as the result of normal bacterial proliferation and gas production which however occurs too late to be of any diagnostic value.

It was found in the present investigation that the lower the obstruction the greater was the accumulation of gas and fluid (Figs. 7 and 10). This may be due to the fact that as a rule in the lower obstructions the blood supply of a greater length of intestine was interfered with than in the higher obstructions. Also in the lower obstructions more gas which can be forced into the dilated parietic portion of strangulated bowel may form proximal to the obstruction. It may seem that roentgenography is of relatively less value in obstructions high in the intestinal tract than in low obstructions because the X ray evidences of low obstructions are more

marked than those of high obstructions. However in the present investigation it was shown that as early as 1 hour after the production of the high strangulated obstructions there was sufficient accumulation of gas to make a positive diagnosis of ileus. Moreover as early as 3 hours after the production of the obstruction there was in addition considerable accumulation of fluid.

The relative values of obtaining roentgenograms of the abdomen in the routine anteroposterior position with the patient in the supine position or obtaining them in such a way that the fluid levels could be visualized has been disputed. The author has always felt that roentgenograms demonstrating fluid levels are more valuable than those in which only accumulations of gas can be shown. In the present investigation, however it is demonstrated that the accumulation of gas occurs earlier and is more marked than is the accumulation of fluid. It is also evident that the earliest roentgenographic findings in ileus both of the simple and strangulated varieties is gaseous dilatation of the bowel proximal to the obstruction which can be demonstrated in the roentgenogram taken in the ordinary manner. In those obstructions which had existed longer than 3 hours, however, there was sufficient accumulation of fluid so that

Fig. 1. Graphic representation illustrating the relative amounts of gas accumulation in the bowel in simple and strangulated obstructions of the jejunum and the ileum, as demonstrated roentgenologically at varying periods after the production of the obstruction.

multiple fluid levels could be demonstrated. Even though gas accumulated earlier and more rapidly than fluid in both simple and strangulated intestinal obstructions the author still believes that because when fluid levels can be demonstrated they produce such a typical pathognomonic picture, roentgenograms when possible should be made in such a way that fluid levels may be visualized. Such roentgenograms can be obtained with relatively little difficulty even in the extremely ill patient either by obtaining a lateral roentgenogram with the patient in the supine position or an anteroposterior roentgenogram with the patient lying on the side. In the majority of instances, patients are not too ill to assume the sitting position so that an anteroposterior roentgenogram can be obtained. In this way roentgenograms can demonstrate the junction between the fluid below and the gas above which is of diagnostic importance. Even though the obstruction is of such short duration that an accumulation of fluid has not occurred, gaseous distention can be visualized on roentgenograms taken in this way as readily as in roentgenograms taken in the ordinary position.

Significant is the finding that in the majority of observations in the present investigation and in all of those in which the obstruction had existed 4 or more hours, there was an accumulation of gas in the colon distal to the obstruction. This is undoubtedly due to a reflex dilatation of the colon. It occurred

much more frequently in the strangulated obstructions than in the simple obstructions. The degree of gaseous distentions varied considerably and did not progressively increase with the time interval as did the amount of gas proximal to the obstruction. This was probably due to the fact that from time to time passage of flatus may have occurred from the colon distal to the obstruction. Goehl, Lynch, Borman and Wangenstein observed dilatation of the intestine distal to a strangulated loop of gut and compared it to the paralytic ileus which accompanies peritonitis.

SUMMARY

1. Plain roentgenograms of the abdomen in cases of ileus are extremely valuable as an early diagnostic procedure.

2. The earliest roentgenographic evidence of obstruction consists of an accumulation of gas proximal to the point of obstruction. Gas accumulation occurred earlier and was more marked than was fluid accumulation.

3. In simple obstructions of the jejunum as early as 3 hours and in strangulated obstructions of the jejunum as early as 1 hour after the onset of obstruction there was sufficient gas accumulation to diagnose ileus roentgenologically.

4. In both simple and strangulated obstructions of the ileum there was sufficient accumulation of gas as early as 1 hour after the production of the obstruction to make possible a positive X-ray diagnosis. However the accumulation of gas and fluid was more marked in strangulated than in simple obstructions.

5. The accumulations of gas and fluid were apparently greater the lower the site of obstruction and were more marked in strangulated than in simple obstructions.

THE APPLICATION OF SURGERY TO THE HYPOGLYCÆMIC STATE DUE TO ISLET TUMORS OF THE PANCREAS AND TO OTHER CONDITIONS¹

EVARTS A. GRAHAM, M.D., F.A.C.S. AND NATHAN A. WOMACK, M.D. ST. LOUIS, MISSOURI
From the Department of Surgery, Washington University School of Medicine and Barnes Hospital, St. Louis

THE subject which I have selected to discuss in this the fourth annual Arthur Dean Bevan lecture seemed to me a particularly appropriate one because much of the pioneer work which has attracted attention to the possibility of the surgical relief of this condition has been done by those who have in some way been identified with this city (Chicago). I refer especially to the careful and painstaking work of Rollin Woodyatt on sugar metabolism to the important cytological investigations of Bensley and finally to the careful study by Russell Wilder of a case of carcinoma of the islands of Langerhans which was associated with evidence of hypoglycæmia. A particular reason however for selecting this subject was the fact that in the last few years at the Barnes Hospital we have had the unusual experience of encountering 6 cases of proved tumor of the islet tissue. In 3 of these the patients were operated upon with successful results and in the 3 others in which no operation was performed the tumors were found at autopsy. In addition the material obtained at an autopsy at another hospital has been studied by our department of pathology.

Before the discussion of the subject in detail it may be well briefly to review our current conceptions of the regulation of the sugar in the blood. The sugar equilibrium is maintained by the counterplay under nervous control of a number of factors of which the secretions of several glands are perhaps the most important. Insulin from the islands of Langerhans of the pancreas tends to diminish the amount of blood sugar and on the other hand, the secretions from the medulla of the adrenal gland from the anterior lobe of the pituitary² and from the thyroid all tend to

increase it. Despite the antagonistic action of several forces the amount of the blood sugar in normal fasting individuals, that is before breakfast, does not vary greatly but is usually found to be about 0.10 per cent. or about 100 milligrams of sugar in 100 cubic centimeters of blood.

The introduction of insulin as a therapeutic agent was soon followed by dramatic demonstrations of the danger which may arise from reducing the amount of the blood sugar too far below the normal level. Accordingly a syndrome of hypoglycæmia has become recognized. The clinical manifestations of this condition are numerous. It is necessary to mention some of these in order to understand the picture presented by an active tumor of the islands of Langerhans.

The most commonly observed symptoms of hypoglycæmia are a feeling of malaise, lassitude, inability to perform mental or physical work often accompanied by trembling and sweating. The face may be alternately pale and flushed. There may be a fall in temperature. Simultaneously with these symptoms there is usually a sensation of hunger which may be extreme and even agonizing. Carlson and his associates have shown that hypoglycæmia is associated with violent contractions of the stomach. One of Harris's patients states that he felt as if he would die if he could not have food immediately. Yawning and mental confusion often accompany the sensation of severe hunger. The pulse is usually accelerated. But some of the most important and striking symptoms are related to the nervous system. Mental confusion resembling alcohol intoxication is very common and crises resembling epileptic convulsions have been noted so often that the first diagnosis made in several of the reported cases of islet tumors has been that of epilepsy. In most cases however it can be

¹Ordinary commercial pituitary extract which is made mostly from the posterior lobe also increases the blood sugar. The action of adrenalin is supposed to be due to the liberation of sugar from glycogen stored in the liver.

This paper was given by the senior author at the fourth annual Arthur Dean Bevan Lecture before the Chicago Surgical Society and the Chicago Institute of Medicine on December 14, 1921.

noted that the crises are different from those of true epilepsy of the grand mal type. Sigwald in a recent excellent monograph on hypoglycemia states "Most often these attacks are partial limited intermittent and irregular, the contractions have abnormal characteristics, one can observe hysteriform crises with contracture in the arc of a circle and great agitation or tetaniform crises with permanent contracture in opisthotonus or in another attitude. These extensive convulsions deserve the name of 'epileptiform crises.' Convulsions limited to one side of the body and even to the face or to the extremities have been recorded. Amnesia is another common symptom of great value. The patients seldom remember what they have done or said during the periods of mental and psychic abnormality. In some cases even localizing signs of disorder of the central nervous system such as a Babinski sign, disturbances of the pupils etc. have been noted in connection with the hypoglycemic state. In the more severe cases, coma is frequently observed. It is unnecessary to enumerate all of the various clinical phenomena which have been found to be associated with a state of hypoglycemia. It is important, however, to emphasize that in many cases the neurological or psychiatric aspects of the condition are so prominent that many of the patients with chronic hypoglycemia have been referred primarily to neurologists and psychiatrists for treatment. Sigwald refers to several recent reports of chronic psychoses in patients who were taking insulin which disappeared at once after the cessation of insulin treatment. It is interesting also that repeated observations have been made of hemorrhages into the central nervous system in severe induced hypoglycemia. This observation perhaps has a special bearing on one of our cases which will be noted later.

There is, of course, no definite level of the blood sugar at which the symptoms of hypoglycemia are likely to appear. In general, however, the most severe manifestations are associated with the lowest findings of blood sugar. When the blood sugar diminishes to 50 milligrams or less per 100 cubic centimeters, the effects are likely to be severe.

Apparently the first suggestion of the possibility that the blood sugar might be excessively lowered spontaneously by an abnormal activity of the islet tissue of the pancreas was made by Seale Harris of Birmingham, Alabama, in 1924, in a paper entitled "Hyperinsulinism and Dysinsulinism." In this paper he reported 12 patients with blood sugar values of less than 70 milligrams nearly all of whom presented many of the symptoms which have already been described as those associated with hypoglycemia. Since one does not find such low blood sugar values in starvation he concluded that probably they represented an expression of spontaneous hyperinsulinism. Jonas in the following year added another case in which because the most striking symptoms were epileptiform the patient was sent to an institution for epileptics and died there. This same case was later reported by Hartman.

The most striking evidence however of the occurrence of hyperinsulinism or dysinsulinism was presented in 1927 in the important report by Wilder, Allan Power and Robertson of their dramatic case. This concerned a man, 40 years old who for more than 2 years had had attacks consisting of syncope, parasthesia of the tongue and lips, asthenia, sweats and trembling. These attacks occurred just before a meal or after unaccustomed exercise and the patient had discovered that he could escape them by taking food or sweetened drinks. On one occasion he was comatose for a couple of hours and had been revived by injections of adrenalin and of dextrose. A sugar tolerance test showed a rise from 85 to 215 milligrams per cent at the end of a half hour and then a fall to 31 milligrams per cent three hours later. Finally it was calculated that this patient required as much as 25 grams of dextrose per hour to avoid his attacks. An exploratory operation by W. J. Mayo revealed a large nodular pancreas with metastatic tumors in the liver. From tissue recovered at autopsy a month later the tumor was found to be a primary carcinoma of the islands of Langerhans, and it was found to contain as much as 40 units of insulin to 100 grams of tumor. In the following year (1928) Thalhimer and Murphy

THE APPLICATION OF SURGERY TO THE HYPOGLYCÆMIC STATE DUE TO ISLET TUMORS OF THE PANCREAS AND TO OTHER CONDITIONS¹

EVARTS A. GRAHAM, M.D. F.A.C.S. AND NATHAN A. WOMACK, M.D. St. Louis, Missouri
From the Department of Surgery, Washington University School of Medicine and Barnes Hospital, St. Louis

THE subject which I have selected to discuss in this the fourth annual Arthur Dean Bevan lecture seemed to me a particularly appropriate one because much of the pioneer work which has attracted attention to the possibility of the surgical relief of this condition has been done by those who have in some way been identified with this city (Chicago). I refer especially to the careful and painstaking work of Rollin Woodyatt on sugar metabolism to the important cytological investigations of Bensley, and finally to the careful study by Russell Wilder of a case of carcinoma of the islands of Langerhans which was associated with evidence of hypoglycemia. My particular reason however for selecting this subject was the fact that in the last few years at the Barnes Hospital we have had the unusual experience of encountering 6 cases of proved tumor of the islet tissue. In 3 of these the patients were operated upon with successful results and in the 3 others in which no operation was performed the tumors were found at autopsy. In addition the material obtained at an autopsy at another hospital has been studied by our department of pathology.

Before the discussion of the subject in detail it may be well briefly to review our current conceptions of the regulation of the sugar in the blood. The sugar equilibrium is maintained by the counterplay under nervous control of a number of factors of which the secretions of several glands are perhaps the most important. Insulin from the islands of Langerhans of the pancreas tends to diminish the amount of blood sugar and on the other hand, the secretions from the medulla of the adrenal gland from the anterior lobe of the pituitary² and from the thyroid all tend to

increase it. Despite the antagonistic action of several forces the amount of the blood sugar in normal fasting individuals, that is before breakfast does not vary greatly but is usually found to be about 80 per cent or about 100 milligrams of sugar in 100 cubic centimeters of blood.

The introduction of insulin as a therapeutic agent was soon followed by dramatic demonstrations of the danger which may arise from reducing the amount of the blood sugar too far below the normal level. Accordingly a syndrome of hypoglycemia has become recognized. The clinical manifestations of this condition are numerous. It is necessary to mention some of these in order to understand the picture presented by an active tumor of the islands of Langerhans.

The most commonly observed symptoms of hypoglycemia are a feeling of malaise lassitude inability to perform mental or physical work often accompanied by trembling and sweating. The face may be alternately pale and flushed. There may be a fall in temperature. Simultaneously with these symptoms there is usually a sensation of hunger which may be extreme and even agonizing. Carlson and his associates have shown that hypoglycemia is associated with violent contractions of the stomach. nodule which measured 1 centimeter in diameter. The authors as well as Dr. Bensley, who also examined the tissue, believe from the microscopic appearance that it is a true tumor and not merely a hypertrophic island. Because of their inability to demonstrate either alpha or beta granules in the cells it was decided that this was not an active tumor. Certainly there was no clinical evidence of activity because the patient had severe diabetes instead of hypoglycemia. Thus of the 4 cases one was definitely associated with hypoglycemia, another had symptoms suggestive of it, a third had no clinical evidence of it but the amount of the blood sugar had not been determined and in the fourth the patient had severe diabetes instead of hypoglycemia.

In 1928 MacClenahan and Norris had reported their very definite case of adenoma associated with severe signs and symptoms of hypoglycemia in a man 42 years old. At autopsy the tumor which was 1.6 centimeters in diameter was found to be plainly encapsulated. There were no mitotic figures and the cells for the most part resembled beta cells of normal islands. Neighboring pancreatic tissue showed some hypertrophied islands.

Since October 1930 3 patients have been successfully operated on at Barnes Hospital for the removal of a tumor of the pancreas associated with marked hypoglycemia.

The first case, which has been reported by Parker, Grove, Fisher and Langerhans, was a young man of 19, a student at a medical school, who was referred to the neurologic department by a physician who diagnosed the condition as epilepsy because of repeated seizures which had been present for a year. It was worthy that these attacks occurred at breakfast. Under the strict discipline of the school these attacks had been controlled, and even on occasions when they occurred the boy was often noted as getting dressed and at the hospital on several occasions he had been treated by plenary measures. On one occasion he was in the streets of a large city and had an accident and had no recollection of what had happened. When he was in various attacks he was always hungry. Food, especially sweets, seemed to relieve the attacks. Blood taken during the hospital showed only 46 per cent per 100 cubic centimeters. A 1.5 centimeter tumor was made. At autopsy on October 22, 1930 Dr. A. J. Well encapsulated adenoma from

Fig. 5 Low power view of the tumor removed at the first operation. This was probably much older than the second tumor removed from the same patient later. See text for discussion of it. (Barnes Hospital Case 3)

border of the pancreas at about its midportion. The tumor was somewhat larger than most of those which have been described, measuring 2 centimeters in long diameter. The postoperative course was uneventful, the blood sugar was promptly restored to a normal level, and the patient's symptoms have been entirely relieved.

Our second operative case has also been separately reported. It concerned a farmer, aged 44 years, who had been in good health until October 1929. One morning at this time he noticed that while doing his chores about the farm before breakfast he became mentally confused. He described the symptoms as similar to those of alcoholic intoxication. After eating breakfast he felt normal again. His next attack was early in the morning about 1 week later when he noticed the same sort of feeling. Attacks began to be more frequent and a little more severe. Early in December 1929 he had his first very severe attack, at which time he became unconscious and had to be carried into the house. He was given food and in a few moments was feeling normal again. His memory as to what took place during this seizure was considerably confused. He consulted his family physician who could find nothing abnormal on physical examination. During the next 2 months the patient was examined at two different clinics, where the diagnosis of a possible brain tumor was made. He was given phenobarbital, with no improvement. He now began having attacks before rising in the morning during which, according to his wife, he became much confused spoke at random, and at times fell from his bed. She also noticed twitching movements, especially about the face. There were never any generalized convulsions. At another clinic it was found that he had a patho-

logical condition of the gall bladder and this organ was removed along with the appendix. There was no amelioration of the symptoms. It was at this time that his wife noticed that, if she fed him several times at night, his attacks could be prevented. He also began carrying candy around in his pockets during the day and noticed that frequent eating of it prevented the seizures. He was referred to us in January 1931 for study. Drs. Womack and Gnagl had made a tentative diagnosis of an islet tumor on the basis of the patient's history before he entered the Barnes Hospital for study.

General physical examination gave entirely negative results. The blood pressure was 128 systolic and 74 diastolic. There were no positive neurological observations. The disks were normal, as were the visual fields. Roentgenograms of the skull were indeterminate. The basal metabolism rate was plus 3 per cent. The urine was normal red blood cells 5,230,000, and white blood cells 6,600. The differential count was normal. Hemoglobin was 90 per cent. The Wassermann and Kahn reactions of the blood were both negative. Phenolsulphone phthalein excretion was 80 per cent in 1 hour. The blood amylase determination by Elman's method was 7.5 units (5 units normal). Blood non-protein nitrogen was 27 milligrams per hundred cubic centimeters.

The patient was given his regular evening meal. This was followed by 300 cubic centimeters of milk at 7 p.m. and 300 cubic centimeters of sweetened grape juice at 9 p.m. He was not given any more food that evening. At 6:15 a.m. he was found to be awake. His face was expressionless, his pupils somewhat dilated and though he answered when spoken to, his answers were incoherent. There was a generalized coarse tremor and the respirations were mildly Blot in character. A specimen of blood was taken for a sugar determination. The patient was then given 120 grams of dextrose by mouth (estimated weight 150 pounds or 68 kilograms). Ten minutes after receiving the dextrose he was again alert and did not remember any of the preceding events. No more food was given and blood specimens were taken at hourly intervals. At the end of 7 hours he again became slightly confused, began to perspire. It was noted that the reflexes were slightly hyperactive. He soon presented the same clinical picture that he had presented earlier in the morning, and further food was given, with immediate relief. The foregoing description is that of a fairly typical attack and was observed on several occasions.

The reaction to epinephrine was found to be a definite one. The patient was temporarily relieved of his confused state and showed at the same time a rise in blood sugar.

The reaction of pituitary extract was delayed and irregular though there was a slight rise in blood sugar.

February 4, a laparotomy was performed (E.A.G.) The pancreas was exposed through the gastro-

Fig. 6 left. Second tumor from same patient as Figure 5. Imperfectly formed lobules and sinuous cords of epithelioid cells. Hematoxylin and eosin stain. High power (Barnes Hospital, Case 3.)

colic omentum and at about the junction of the body with the tail on the anterior surface a small tumor was seen about one centimeter in diameter. It showed through the posterior peritoneum as a dark spot suggestive of a small hemorrhagic area. It felt firm. When the peritoneum was incised it was found that the tumor could not be shelled out of the pancreatic tissue and it was therefore necessary to dissect it out with a small margin of normal pancreatic tissue around it. Before this was done a pursestring suture was placed in the substance of the pancreas in order to control hemorrhage. The vessels in the region of the tumor were all enlarged. The edges of the tumor bed were brought together and the peritoneum was then closed over. A small rubber drain was placed over this and brought out through the left side of the abdomen by means of a stab wound.

Convalescence was somewhat stormy at first. Immediately after the operation a pulmonary infection developed which however was not very severe. On the second day after operation there was a fairly rapid edema of the lungs. The patient was placed in an oxygen tent and given atropine. His condition improved rapidly. A pancreatic fistula developed several days later. This did not cause any skin excoriation and was rapidly closing at the time he left the hospital. Since his operation he has not had any more attacks, although his diet has been one containing no more carbohydrate than that of a normal individual. Fasting for 12 hours has failed to bring on an attack. In fact the blood sugar at this time was 99 milligrams per hundred cubic centimeters. At no time since operation has it been lower than this. We saw this patient again in December, 1932

nearly 2 years after his operation. He was in excellent health and he stated that he had had no further attacks of his former trouble.

We were fortunate in being able to submit the tumor tissue to Prof. R. R. Bensley of the University of Chicago who was present at the time as a visiting professor of anatomy in Washington University. Dr. Bensley is recognized as an authority on the cytology of the pancreas. Excerpts from his report follow. While examination of the fresh cells was in progress, another portion of the fresh material was stained with neutral red in a 1:10,000 concentration in physiological solution of sodium chloride. It should be remarked that when normal islands of Langerhans are so treated the minute granules which the cells contain stain rapidly a bright yellowish red color with the neutral red. The cells of the tumor showed with the neutral red a curious reaction which was observed also in the case reported by Carr, Parker, Grove, Fisher and Larimore. In that case the granules in groups of cells stained intensely with neutral red, while other groups of cells clearly containing granules failed to stain. Other cells of the same tumor showed scattered granules staining with neutral red dispersed among other granules which failed to stain.

"I was of the opinion when I examined this first tumor that the failure of the neutral red to stain every cell was due to the mechanical difficulty of penetration of the dye but the examination of the present tumor in which by the experience gained in the study of the first it was possible to take precautions to avoid this, indicates that in both tumors there are granules present which stain readily with neutral red and other granules which do not stain

with neutral red. In the tumor now under description scattered cells, not in groups, stained exactly as a normal beta cell of the islands of Langerhans—that is to say, the cells were packed with granules which stained brightly with neutral red. These cells did not occur in groups, as in the Carr-Parker-Grove-Fisher-Larimore case but were individual. Many cells contained scattered neutral red stained granules mingled with granules of about equal size which refused to stain but the majority of the cells contained granules which stained only faintly with neutral red.

Two other observations were noted in all the cells of the tumor: a few granules, about the size of a zymogen granule, in the pancreatic acinus, more highly refractive than the regular granules and staining brightly with neutral red; a few cells contained rather indistinctly outlined amorphous bodies which stained rather faintly with neutral red. As the preparation became old, the cells behaved like island cells under similar circumstances: vacuoles formed in the cytoplasm, and the granules disappeared.

The tumor was slightly irregular in outline and, as already mentioned, was not encapsulated. At portions of the surface it was separated by broad strands of collagenous connective tissue from the neighboring pancreatic lobules, but at other points it was actually in contact with pancreatic tissue and at one point in the tumor the pancreatic acinus tissue was not only in contact with the tumor tissue but was actually in epithelial continuity with it.

The substance of the tumor itself was imperfectly divided into lobular masses by heavy strands of collagenous connective tissue. In these bands, portions of pancreatic ducts were seen and, in addition, masses which presented the appearance found in lobules of a pancreas whose ducts have been

ligated. In the latter masses, regenerated acinus cells, such as those which have been described by Grauer in his account of regeneration in the pancreas of the rabbit, were to be seen. There were also present in this tissue small and large groups of normal island cells, also probably of recent origin.

The acinus cells seen in these complexes had evidently arisen by differentiation from duct epithelium since they presented all grades of advance in the regenerative processes as follows: (1) individual acinus cells surrounded on all sides by duct epithelium; (2) groups of two or three acinus cells; and (3) well individualized small acini. Ducts were in many places continuous with the epithelial masses of the tumor itself. The tumor tissue presented different aspects in its different parts, and these different aspects I conceive to be the different stages in the progress of this growth.

One lobe separated from the others by strands of connective tissue presented the appearance of an enormous, overgrown island of Langerhans, except, as appeared later, for the fact that the cells which composed it were not normal island cells of either category but abnormal tumor cells of island reference. This portion of the tumor consisted of anastomosing cords of epithelial cells separated by wide sinusoidal capillaries, the endothelium of which was almost in contact with the epithelial groups, a minimum of reticular connective tissue being interposed.

In the adjacent portion of the tumor the proliferation of the epithelial elements had exceeded the rate of growth of the vascular components, and in this portion of the tumor an extraordinarily large mass of epithelium was traversed only by a normal number of capillary blood vessels, and these showed a tendency to become separated from the epithelial elements by an increase in the layer of connective

tissue outside of the endothelial tube. In some of these cellular masses there was a breakdown of cells forming spaces containing scattered necrotic epithelial cells and much blood, the blood vessels having evidently ruptured into the space provided by the death and dissolution of the epithelial cells.

In the third section of the tumor an appearance which approached that in the Carr Parker Grove Fisher Larimore case was attained. Groups of epithelial cells were separated from one another by wide strands of hyalinized connective tissue containing blood vessels. Degenerative processes in this tumor were not nearly so manifest as in the tumor removed by Dr. Fisher, but in places the cells had completely broken down and the place formerly occupied by them was now filled with blood, a few scattered epithelial cells and in some instances isolated groups of tumor cells attached to the walls.

Sections of material fixed in chrome sublimate and in formal Zenker stained with Bowie's stain or Bensley's neutral gentian revealed the fact that only a small proportion of the cells of the tumor had the characteristics of normal beta cells.

Examination of the material fixed in chrome sublimate or formal Zenker stained with neutral gentian or with Bowie's stain showed that many cells in this tumor contain beta granules associated with granules of another sort. This observation recalls that made by Robinson that in his tumor some cells contained both alpha and beta granules.

The cytologic study of this and of the preceding tumor and of the one reported by Robinson, indicates that in this case the tumor is not one composed of normal island cells but on the contrary one composed of cells which, while having a considerable resemblance to island cells, yet differ from them in important details. These differences consist of the production of a granular secretion antecedent, which differs in important details from the normal content of the island cells, and in the presence in these cells of a chromophil substance unusual to island cells and found in normal pancreas only in acinus cells.

The normal pancreas as is well known contains a very considerable excess of island tissue and yet ordinarily does not yield to the general circulation an excess of insulin. The fact that a tumor of such meager proportions could produce the symptoms of insulin shock and yet not be responsive as the normal islands are to the mechanisms that ordinarily regulate the export of insulin from the pancreas, is possibly to be found in the fact that the lesion under discussion is an abnormal cell type which, to be sure, resembles island cells but is not identical with them.

Some doubt exists in my mind as to whether this tumor should be regarded as adenoma or carcinoma. The failure to form a definite capsule and the inclusion of normal pancreatic elements in the tumor itself seem to favor the latter diagnosis.

Our third and last case presents the unique feature of having two tumors and two opera-

tions for their removal with a final successful outcome. This case has not been reported elsewhere.

A young man aged 22 years of Jewish extraction was first admitted to the Barnes Hospital on March 14, 1928 on the neurological service for the diagnosis of epilepsy.

He had had tuberculosis of the hip at the age of 3 for which he wore casts and braces until the age of 13, scarlet fever at the age of 15. In 1926 at the age of 20 he graduated from the St. Louis School of Pharmacy, apparently a fairly capable student and since then has been working as a druggist.

In March 1927 he noticed twitching in his legs after walking a few blocks. This occurred particularly at the end of his day's work when walking home from his drug store which usually occurred just before dinner. After dinner he could walk a much longer distance without observing any twitching of his legs. In January 1928 he noticed a similar twitching of his arms just before dinner and with this there was a feeling of drawing of his face associated with pallor and sweating. On one occasion he stared straight ahead for a minute or two and after being put to bed made an immediate recovery from these symptoms. In February 1928, he had several fairly typical attacks of petit mal which lasted from 3 to 5 minutes. There were no after effects but often there was a feeling of nervousness and weakness just preceding the attacks.

Upon admission to the hospital the patient was found to be intelligent and co-operative. His memory was good and he appeared to be interested in the examination, appearing neither depressed or excited. There was a slight slurring of speech and occasional twitching movements of various muscle groups. His gait was what was to be expected from the ankylosis of the left hip with a scoliosis. The blood pressure was 110-60 the pulse 70. A nystagmus was present and a discharge from the right ear, apparently from a chronic mastoiditis. No blood sugar determination or blood chemistry was done. All the routine laboratory work including a blood Wassermann, was negative. The patient was considered atypical of epilepsy and was discharged for further observation.

Three months later he was readmitted to the hospital with no apparent change in his condition. At this time a tonsillectomy was performed.

On January 30, 1931 the patient was readmitted to the hospital. During the past year the attacks had become more frequent and more severe. Examination at this time showed him to be still intelligent and co-operative. No blood chemistry determinations were made because of certain observations by the psychiatrist who was taking care of him at this time and who thought his condition to be due to sexual repressions. He was treated by psychoanalysis and hypnotism with no apparent improvement.

On August 8 1931 he was again admitted to the hospital and on questioning him at this time the patient gave only nonsensical answers. His attacks continued to be severe. No additional positive findings were noted on examination.

On May 9 1932 he was readmitted to the hospital for the fifth time. He had now begun to have several attacks a day of petit mal. There was also a progressive muscular weakness. He entered the hospital during one of his attacks of petit mal. A sample of blood was taken immediately and the sugar was found to be only 35 milligrams per hundred cubic centimeters. The blood calcium was 3.5 and the phosphorus 10.6. He was given 50 cubic centimeters of 50 per cent glucose intravenously immediately. After receiving the first 25 cubic centimeters he aroused and was able to answer questions. When all of the 50 cubic centimeters had been received he was able to sit up and talk intelligently. His memory of the attack was poor. He had entered the hospital in the evening and after receiving the intravenous glucose he was given sweetened fruit juices to drink. On the following morning at 5 o'clock he had another seizure which disappeared 10 minutes after drinking a glass of orange juice.

On May 11 carbon dioxide combining power of blood was 73.51 per cent, calcium 10.9 milligrams per cent, phosphorus 3.6 milligrams per cent.

A sugar tolerance test was performed with the following result:

Milligrams
per cent

7-45 a.m. fasting blood sugar	58
8-15 a.m. glucose	
8-40 a.m.	312
9-10 a.m.	133
10-10 a.m.	117
11-10 a.m.	60
12-10 p.m.	53
1-10 p.m.	43
2-10 p.m.	40

Urine collected from 8-40 a.m. to 11-10 a.m. negative for sugar.

On May 13 the patient was found by Miss Kendall to have an intelligence quotient of 60. Her conclusions state, "this is evidently not representative of patient's original intellectual endowment. Scattered distribution of success and failure, the relatively high vocabulary and the difficult co-operation would indicate this even if the history were not known. Objective findings, Stanford lowest failures all in reversing digits and in making sentences to include three given words (9 years). The best work in inductive reasoning (14 years) and in vocabulary (12 years)."

On May 19 after receiving 500 cubic centimeters of 10 per cent glucose intravenously a laparotomy was performed (E.A.G.) An upper left paramedian

incision was made and the pancreas was exposed through the gastrohepatic omentum. A small hard tumor was immediately felt and seen on the anterior surface of the pancreas at about the junction of the left and middle thirds. The tumor was clearly exposed and was seen to project slightly forward. One portion of it was so hard that it suggested calcification. There was a slight bluish discoloration of the tumor which made it distinct in appearance from the rest of the pancreas. A pursestring suture of catgut was placed around the tumor bed and the tumor removed. This was easily accomplished and there was only one small vessel at the pedicle. It was not necessary to remove any appreciable part of the normal pancreatic tissue. When removed the tumor was found to be about 1 by 0.8 cubic centimeters. It was immediately placed in fixing fluid, a rubber dam drain was inserted down to the pancreas and the wound was closed in layers. The operation was prolonged because of frequent attacks of apnea. The anesthesia used was nitrous oxide-oxygen with a little ether.

At 11 a.m. (immediately following the operation) the blood sugar was 100 milligrams per cent. Five hundred cubic centimeters of 10 per cent glucose were given intravenously followed by 3,000 cubic centimeters of physiological saline solution subcutaneously.

At 3 p.m. the blood sugar was 212 milligrams per cent. 4 p.m. the blood sugar was 170 milligrams per cent.

May 20, 9 a.m., the blood sugar was 122 milligrams per cent, no convulsions had occurred, 500 cubic centimeters of 10 per cent glucose were given intravenously.

May 21, 9 a.m., the blood sugar was 96 milligrams per cent (fasting). Five hundred cubic centimeters 10 per cent glucose given intravenously.

May 23, 9 a.m., blood sugar 102 milligrams per cent (fasting). Blood calcium 9.6. Blood phosphorus 2.9. Later in the day he had a convulsion, the first since his operation. He was given some fruit juices during the day by nasal tube.

May 24, 9 a.m., blood sugar 34 milligrams per cent (fasting). Carbon dioxide combining power 69.7 volumes per cent. The patient had another convulsion which was controlled by the drinking of fruit juice.

From then on during the next few days the patient was given large amounts of carbohydrates until on May 28 he was receiving 600 grams of carbohydrate per 24 hours. Although there had been no convulsions since May 24 the patient had been apathetic, incontinent, with hyperactive reflexes and a peculiar muscular rigidity associated with carpal spasm suggestive of tetany. This latter phenomenon had been noted before the operation but it had never been associated with an abnormally low blood calcium. The patient now developed an extreme mental confusion. On June 7 a note was made that the electrocardiographic record showed simple tachycardia. Roentgenogram showed normal sella. No changes in

The diagnosis of probable pancreatic tumor and the suggestion to perform the operation were made by Drs. Barr, Alexander, Brewster, Parker, Grove and others.

eye grounds. A previous examination of the visual fields gave normal findings. The blood pressure readings were always practically normal.

From this time on in spite of large amounts of carbohydrate the patient's condition became steadily worse. On June 5 the note was made that he was stuporose although responding slightly to cutaneous stimuli. There was slight cyanosis and the respirations were only 5 per minute. This recalled the periods of apnea noticed at the operation. There had been no convulsions during the last few days but there was bilateral ankle clonus and slight rigidity of the left lower extremity. Because of a suggestion made in the report of Wilder et al that perhaps ether anesthesia increased the blood sugar and in view of the temporary improvement noticed in our patient after the operation it was decided to subject him to another anesthesia. At the beginning of the anesthesia which was at the end of a 7 hour fast his blood sugar was 40 milligrams per cent. At the end of 50 minutes of anesthesia his blood sugar was 45 milligrams per cent and 1 hour later it was 54 per cent. Three hours later however while still fasting the blood sugar had fallen to 22 milligrams per cent. During the next few days in spite of high carbohydrate feeding convulsions were frequent and the patient became increasingly worse. Tests to demonstrate insulin in the urine made by Dr. Kuoymann of the department of biochemistry uniformly were negative, concentrated urine ammonium sulphate precipitation and alcoholic extraction being used.

Because it was felt that we had failed to find the active tumor responsible for the patient's condition especially in view of the results of the microscopic examination of the tumor which had been removed which will be described later the question of operating on the patient again was discussed. It was felt that unless another operation revealed an active tumor the patient would almost certainly die and that therefore another operation was plainly indicated. Accordingly on July 14, 1932 after the patient had been given 500 cubic centimeters of 20 per cent glucose intravenously the abdomen was reopened through an incision just to the left of the former incision and the pancreas was exposed again all along the anterior surface through the gastrohepatic omentum. Nothing resembling a tumor was found on the anterior surface. The tail was then mobilized and rotated forward. Within the substance of the tail but not visible on the surface, a nodule was felt which was firmer than the rest of the pancreatic tissue. This could be felt only by palpation of the organ between the thumb and index finger. It was closer to the posterior than to the anterior surface. It was about 2 centimeters in long diameter. It was removed together with about 4 centimeters of the tail. In cutting through the nodule after its removal a rather homogeneous appearance was noted on cross section which made it seem certain that the nodule was composed of tumor tissue. The remainder of the organ was examined as

far toward the head as possible but no evidence of other tumors was found. Both adrenal glands were felt and found to be of normal size. The liver appeared to be normal but a small piece was removed for microscopic examination which was later found to be normal. The stump of the pancreas was closed over itself with chromic catgut. Immediately after the operation the blood sugar was 235 milligrams per cent. Another intravenous injection of 500 cubic centimeters 10 per cent glucose was given. Ten hours later the blood sugar was 218 milligrams per cent.

From then on the blood sugar remained normal or slightly above normal. On July 18 it was necessary to open the wound slightly to give access to about 50 cubic centimeters of pus which seemed to come from around the pancreas. Except for this complication the postoperative course was uneventful.

On August 9 a note by Dr. A. B. Jones states that there is definite evidence of extrapyramidal tract degeneration.

The patient was discharged on September 14. He had shown very marked and steady improvement since the second operation and there had been no convulsions.

On October 17 he was readmitted to the hospital for observation. His sugar tolerance showed a slight tendency toward diabetes. There had been steady improvement in the patient's mentality and another examination by Miss Kendall at this time showed an intelligence quotient of 71 as compared with 60 on the preceding examination and a gain of 22 months in mental age. The patient was actively interested in everything going on around him and was able to defeat his father and his brother in chess. He was still unable to walk but a very definite improvement in muscle tonus was observed. Some of his difficulty in walking was undoubtedly due to the ankylosis of his hip joint which was noted in the first examination.

It is still uncertain how much additional improvement will occur in this patient's mentality. It seems probable that his central nervous system was more or less permanently damaged by allowing a condition of severe hypoglycemia to continue for too long a time.

Examination of the tumors. The two tumors removed from this patient were examined by Professor Bensley as well as by Dr. O. Leary of our department of anatomy, a former pupil of Bensley's. An abstract of Dr. O. Leary's report which includes both his and Dr. Bensley's opinions follows.

The first tumor measured approximately 1.0 by 0.8 cubic centimeter and was composed of purple red friable tissue surrounding a heavily calcified core. Examination of the fresh material revealed a predominance of lymphocytes with numerous histiocytes, less numerous polymorphonuclears and eosinophiles. In histological section this mass resembled a calcified lymph node with hyalinization. Dr. Bensley to whom the sections were sent to rule out

finally the presence of islet tissue felt that the specimen was a badly sclerosed lymphatic gland with a considerable amount of active reticular tissue proliferation. However it was removed from the substance of the pancreas and its great similarity to the pocket of tissue found in the capsule of the second tumor both in gross and microscopic appearance suggests the possibility that it might at one time have been an active tumor which became atrophied and was completely replaced when the present tumor arose. Supporting this possibility is the extension over a period of 3 years and the finding of a relatively young tumor mass at the last operation.

"The second tumor consisted of an ovoid mass 2.0 by 1.4 by 1.2 cubic centimeters, of firm elastic consistency. No hemorrhagic or necrotic areas were visible but embedded in the capsule was a single nodule of friable purple red tissue, 3 millimeters in diameter. This nodule consisted chiefly of lymphocytes with numerous macrophages and fibroblasts, less numerous polymorphonuclears and eosinophiles. It resembled in structure the first tumor which was removed from the same patient. As the result of an extensive study of the whole tumor after the use of various fixing agents and stains Dr. O'Leary summarizes his examination as follows: "the findings support the conclusion that the tumor removed was an adenoma of the islet type, cytologically very similar to those previously studied by Bensley and others but due to its size and excellent accommodation of tumor growth to vascular supply it was capable of producing relatively more of the hypoglycemic hormone than the previous tumors studied at this institution. In making this diagnosis, questionable evidence of malignancy has been discounted. The deviation of the majority of tumor cells from the beta type gives further affirmation to the dysinsulinism hypothesis.

The detailed report of the second tumor follows:

"When cut it appeared homogeneous throughout, save for strands of fibrous tissue traversing it. No hemorrhagic or necrotic areas were visible. Embedded in the capsule, however, was a single nodule of friable tissue purple red in color and 3 millimeters in diameter. This was dissected free and placed in Ringer's fluid for examination in the fresh. A sagittal block, including tumor tissue and adherent pancreas, was fixed immediately in formal chrome sublimate. Successive slices toward one surface were fixed in aqueous and acetic chrome sublimate, Altmann's and Bouin's fluids and formal absolute alcohol (the latter for micro-incineration). At the same time small bits were preserved in Ringer's fluid and in 0.1 and 0.05 per cent neutral red (Gruebner No. 0539) in normal saline. These bits provided material for the examination of fresh tissue. The remainder of the tumor was set aside for physiological assay.

"The bits of tissue for fresh examination teased with difficulty. Cells did not float free as in the Womack et al. and Carr et al. tumors previously

studied by R. R. Bensley. Even so, groups of cylindrical and polyhedral cells having clear nuclei, prominent nucleoli, their cytoplasm occupied by a haze of tiny granules, could be easily differentiated. To one familiar with the appearance of living islet cells of the pancreas this evidence was almost conclusive that the parenchyma of the tumor consisted of cells closely allied to this type. Prominent canals of Holmgren and refractile droplets could also be distinguished in some of the cells. In the material immersed in neutral red, the granules of but occasional cells colored the characteristic brick red that identifies beta islet cells. That this was not due to mechanical factors is illustrated by the occurrence of these cells among groups of cells whose granules remained uncolored. As compared with the Womack et al. and Carr et al. tumors, the cells whose granules colored by neutral red appeared to be significantly less numerous.

The reddish friable mass removed from one wall of the tumor had a cell content identical with that observed in a preceding mass removed from the pancreas of the same patient. It consisted predominantly of lymphocytes with numerous macrophages and fibroblasts, less numerous polymorphonuclears and eosinophiles. The possible significance of this finding will be discussed later.

"The fixed tissue was sectioned in paraffin at 4/8. The slice through the center of the tumor (formal chrome sublimate fixation) well illustrated the condition that maintained in all but isolated portions of the tumor. Sections from this and other blocks were colored by Mallory's triple stain, the Heidenhain iron-haematoxylin modification of the same. Bensley's and Bowles' neutral stains, hematoxylin and eosin and Delafield's hematoxylin followed by Giemsa's eosin azure. The neutral dyes of Bensley and Bowles, which facilitate the identification of cell types in islet tissue, and the iron-haematoxylin modification of Mallory's connective tissue stain proved to be the most useful.

"When a Mallory slide of the central block was examined it immediately became apparent that the major portion of the tissue closely resembled the beginning tumor stage (classification by Bensley, Womack et al.) of islet cell adenomata, and was remarkably similar to Robinson's description of the condition that prevailed in a tumor of the same type reported by Howland et al. It has a well developed stroma of collagenic connective tissue. Capillaries which issued from the arteries of this framework, carrying with them occasional collagenic fibrils, imperfectly divided the parenchyma into lobules and sinuous cords of epithelioid cells, two to several cell layers in thickness. Figures 6 and 7 illustrate this condition. There was in addition a dense central core of connective tissue and several lesser ones. These contained, besides arteries and veins, ducts of medium to small size and islets of tumor tissue. In the more superficial portions of the fixed material (aqueous and acetic chrome sublimate blocks) the connective tissue was richer in areas than in the

central block but as elsewhere no hyalinization had occurred. Surrounding the tumor was a broken capsule.

Ducts were not of frequent occurrence throughout the tumor. In the central block medium to small sized ones were found in the accumulations of connective tissue and at the surface of the tumor approximating the pancreas. From the connective tissue accumulations the ducts, as well as tongues of islet tissue might be seen to project into the surrounding parenchyma. Figure 8 is a photomicrograph showing the close approximation of duct and islet tissue in the vicinity of the central core. Figure 9 is a higher magnification of the same area. In the region adjacent to the pancreas (central block formal chrome sublimate) the connective tissue partition separating pancreas and tumor was broken by the egress of the ducts. The ducts in this area were differentiating into both islet and acinar cells. All the stages in the differentiation of acinar tissue were there to be observed. In the more superficial blocks of the tumor the capsule between pancreas and tumor was broken and normal pancreas graded into an area of regenerating (?) pancreas, this in turn into tumor. In these blocks ducts were much more numerous throughout the parenchyma and stages in their differentiation into islet cells were apparent.

"The parenchymatous cells of the tumor could be readily recognized as closely akin to the islet variety. Their shape variations were similar they were however most frequently larger in size as compared to normal control islets of the same section. The cytoplasmic granules of occasional cells gave staining reactions identical with those of the beta variety of islet cells. More often in these cells the granules were packed uniformly with the exception of the area occupied by the canals of Holmgren, but in some they appeared to be concentrated at the capillary pole. The cytoplasmic granules of the predominant majority of the tumor cells (henceforth called tumor cells to differentiate them from the beta cells of the tumor) stained differently but differentiation is necessary to explain the effect of coloring with neutral dyes. With Bowie's stain (formol chrome sublimate fixation) scarcely differentiated in absolute alcohol the beta cell granules stained deep blue the tumor cell granules lilac. Slightly better differentiated, the beta cell granules were a lesser blue, the tumor cell granules pink. This transition in colors due to different degrees of differentiation was not so noticeable with Bensley's neutral gentian and here the beta cell granules stained deep purple the tumor cell granules a lighter purple. Tumor cell granules were less closely packed in the cytoplasm the canals of Holmgren could not always be distinguished, and the small vacuoles occasionally seen in the cytoplasm of beta cells were lacking. Only one cell was observed in the tumor whose granules gave the staining reactions of those characteristic of the normal alpha cells of the islets of Langerhans.

Cytoplasmic inclusions of varying shape but identical staining reactions were observed in tumor islet cells. Presumably these were identical with the chromophile material described by Bensley as occurring in the islet cells of all the tumors that he studied. They might be plastered on the outer surface of the nucleus (sickle thickening of Bensley) or occur as discrete bodies in the cytoplasmic mass. The latter were round or spiroidal in appearance. Observed in a mitotically active cell they colored the same as the chromosome mass and could only be distinguished from it by a knowledge of their appearance in resting cells. Dr G. H. Scott informs me that in micro-incinerated sections these inclusions gave evidence of the presence of iron. They did not occur in the cytoplasm of the cells which contained degenerating nuclei. Several typical ones are illustrated in the accompanying photomicrograph Figure 10.

About the margins of the tumor nuclear pyknosis was to be observed. Other evidence of nuclear degeneration also occurred in the body of the tumor. Single cells or patches might be thus affected. Significant of this change was the appearance of clumps of chromatin within the nucleus. All stages between this and complete pyknosis were found. The cytoplasm of cells whose nuclei were thus affected became basophilic and discrete cytoplasmic granules could no longer be distinguished. Cells with hyperchromatic nuclei and those with mitotic figures were infrequently met with. In the cytoplasm of the latter the specific granules of tumor cells though they were reduced in number could be distinguished. Mitotic figures were not observed in beta cells of the tumor.

"The tumor parenchyma gave a negative Masson reaction for argentaffine cells. After 24 hours staining of the granules of histocytes could be observed but the islet cells were free from silver deposit. A control slide of Bouin's fixed intestine showed excellent argentaffine cells.

Insulin assay of second tumor (Dr. A. S. Johnson) A portion of the tumor weighing 0.582 gram was treated according to the method which was found by Best and Jephcott to give the maximum yields of insulin.

The extract was made up to 25 cubic centimeters in a volumetric flask and 10 cubic centimeters were injected into the marginal ear vein of a rabbit. Blood samples taken at various intervals gave the following results:

	Milligram per cent
Initial blood sugar	114
½ hour	92
1 hour	54
2 hours	52

Calculated by the method of Freudenburg the injected extract contained approximately 0.9 rabbit units of insulin.

A second rabbit was given 12 cubic centimeters of

the extract intraperitoneally. The blood sugar values were as follows:

	Milligrams per cent.
Initial blood sugar	117
1 hour	86
2 hours	82
3 hours	46

3½ hours. Convulsions appeared that were relieved by glucose. The tissue analysed therefore contained approximately 40 rabbit units of insulin per gram of tissue. This is 10 times the amount of insulin found in the carcinoma of the islets in the case of Wilder. Allan, Power and Robertson.

This last case not only differs from any of those previously reported in that two tumors were present for the removal of which two operations were performed but there were several other unique features. For example this is the first case in which a tumor was removed which was embedded in the substance of the organ and detected only by palpation instead of by vision. It happened that the second tumor in this case could be found only by palpation. Again it seems surprising that in spite of the evidence of marked activity of this tumor no insulin could be demonstrated in the urine. This is perhaps the more astonishing since the assay of the tumor tissue revealed as much as 4 rabbit units of insulin per gram of tumor tissue, ten times as much as the amount found in the carcinoma of the islets reported by Wilder. Allan, Power and Robertson. Finally also it seems possible that some of the changes in the central nervous system in this case are of a permanent nature which may have resulted from allowing the severe hypoglycæmia to continue for too long a time, or perhaps they may be the result of hæmorrhages which are known to occur sometimes in of severe hypoglycæmia.

Including one case mentioned by Cushing as having been operated on at the Peter Bent Brigham Hospital but concerning which no details have been presented this last case of ours is the fifth one from which a tumor has been successfully removed. Of these 5 cases 3 have been at the Barnes Hospital. It is an interesting fact that in the 4 cases about which the details have been published there has been no mortality. The absence of mortality and the uniformly dramatic nature of

the recoveries constitute an effective plea for more prompt surgical exploration in cases of hypoglycæmia of unexplained origin.

Unfortunately the diagnosis of the presence of an islet tumor is by no means easy. The recognition of a state of chronic hypoglycæmia even with the characteristic symptoms of the condition is not sufficient evidence in itself upon which to make a diagnosis of an islet tumor. Thus for example, other conditions have been found to be associated with the hypoglycæmic state. Phillips, in 1931 reported a case presenting symptoms of severe hypoglycæmia even with loss of consciousness. One determination of the blood sugar was as low as 25. At autopsy in addition to a sub-acute glomerular nephritis the islands of Langerhans were found to be markedly hypertrophied (242 to 318 microns as compared with the normal figures given by MacCallum of 146 to 157 microns). It is well known that disturbances of the adrenal glands may be associated with hypoglycæmia. There are now on record many observations showing that the blood sugar is lowered in Addison's disease and Anderson has reported a case in which there were pronounced symptoms of hypoglycæmia associated with a carcinoma of one adrenal gland. Again also the condition of hypoglycæmia is sometimes associated with certain tumors of the pituitary especially those which arise in the chromophobe cells which manifest adipose-genital symptoms of hypopituitarism. The literature on the association of pituitary lesions with hypoglycæmia is extensively reviewed in Sigwald's monograph. Various diseases of the liver such as primary carcinoma (5, 19) oestrogenamine hepatitis (6) and phosphorus poisoning as well as such a condition as scleroderma (4) are known to be associated with hypoglycæmia. Again other cases, especially in children have been noted in which a clinical picture closely resembling that of an islet tumor has been present but has disappeared spontaneously. Several such cases have been observed at the St. Louis Children's Hospital. For example

M. R., aged 2 years, had been caught by his mother stealing jam and jelly from her cupboard. The small boy was disciplined and the desired sweets were moved to a more secure place which was inaccessible.

cessible to the pitting fingers. On the morning of the second day after the event his mother found it difficult to arouse him. He was brought to the Children's Hospital (September 3, 1931) where he was found to be in coma, with vomiting and acidosis. His blood sugar at the time was only 30 milligrams per cent. He was revived immediately by an intravenous injection of glucose. A sugar tolerance determination on September 5 showed

Fasting	077
1/2 hour	112
1 hour	104
2 hours	109
3 hours	090

Although observed repeatedly since his discharge he has been entirely normal. An operation on his pancreas at the time would have been ill advised. But yet one wonders what the future may show in regard to this child.

It is therefore apparent that the diagnosis of a state of spontaneous hypoglycemia does not in itself establish the diagnosis of an islet tumor. Moreover it will not always be easy for the surgeon to recognize the tumor even when present. If for example it should happen to be embedded in the substance of the pancreas its recognition might be impossible by any justifiable means. Again our last case complicates the situation still more because of the demonstration of more than one tumor a feature which adds an aspect of a possible therapeutic incompleteness if only one tumor has been found and removed. Finally also it would seem now as if sometimes adenomata are present which are inactive. However if an adenoma is found in a patient who has hypoglycemia the chances are very great that the removal of the adenoma will be followed by a marked improvement in the patient's condition.

Several failures to find a tumor at operation in clinically typical cases have now been recorded. In some of these cases attempts to correct the hypothetical condition of hyperinsulinism have been made by the removal of a large part of the pancreas. Such attempts have been made by the Finneys, by Holman and by Allan Boeck and Judd. The results in these cases have been disappointing. Perhaps an active tumor was overlooked and allowed to remain. Moreover it is hardly to be expected that the removal of anything less than nearly all of the pancreas would accomplish a desired result in correcting the

hypoglycemia unless by the removal of a part of the organ an active tumor was inadvertently extirpated. Recently however, Seale Harris has informed us in a letter of a case of "narcolepsy" that was operated upon by Dr. Adrian Taylor for me and the patient was cured clinically by the resection of about half the body and all the tail of the pancreas except the portion attached to the splenic vessels."

Note.—Since the preparation of this manuscript information has reached us that 2 additional cases of islet tumor have been successfully operated upon: one by Schmidt at the University of Wisconsin Hospital and one by Ross and Tomach at the Cleveland City Hospital. These 2 cases bring the number of the total of successful cases of removal of an adenoma to 7, with no reported mortality.

STUDIES ON TUMOR METASTASIS

I. DISTRIBUTION OF METASTASES IN CARCINOMA OF THE CERVIX UTERI

SHEILDS WARREN AND BORROW

From the Laboratories of Pathology of the New England Deaconess Hospital and of the Harvard Cancer Commission

THE distribution of metastases has been studied in a series of 1,059 autopsies on cases of malignant disease taken from the files of the Huntington Memorial Hospital from 1914 to date from the Department of Pathology of the Harvard Medical School from 1920 to date from the House of the Good Samaritan from 1920 to date from the New England Deaconess and Palmer Memorial Hospitals from 1928 to date and from the Pondville Hospital from 1928 to date.

Only those autopsy protocols were utilized which afforded a satisfactory gross description and at least a fair clinical history. No case was included without review of the microscopic slides. For the statistical compilation of much of the data which was facilitated by the use of the punch card system I am indebted to Dr Herbert L. Lombard, director of the Division of Adult Hygiene of the Massachusetts State Department of Public Health, and his assistants.

TABLE I—TYPES OF TREATMENT OF 132 CASES OF CARCINOMA OF CERVIX UTERI AS DETERMINED AT AUTOPSY

Type	Number	No. at pathologic treatment	Operation	Radon	T-ray	Combined	Average total duration, years
Epidermoid I		6	7	9		2	3
Epidermoid II	66		7	20		7	6
Epidermoid III	21	3				6	
Epidermoid not stated							3
Adeno-sarcoma	5						
Adenocarcinoma				9			9

TABLE II—DISTRIBUTION OF METASTASES

Type	Number	No. metastases		Metastases to				
		Number	Per cent	Regional nodes	Distant nodes	Lungs	Liver	Bone
Epidermoid I	5	5	100		7			
Epidermoid II	66	27	40	46	3	8	1	3
Epidermoid III		3	4	7	7	6	9	
Epidermoid not stated		4	100					
Adeno-sarcoma	5			3				
Adenocarcinoma			9	6	6			

Fig. 1. Graph showing percentage of distribution of metastases.

In this series of 1,059 cases are included not only so called active cases of cancer but a large number of terminal care cases as well. Many of the patients were treated others were untreated so an opportunity was afforded to study the behavior of untreated cancer as well as the treated forms of the disease.

Among this group were 132 cases of carcinoma of the cervix uteri.

In Table I is shown the distribution of these cases by histological class and the type of treatment given them. The cases which had no palliative treatment represent those coming to the hospital with far advanced disease or those who for religious or other reasons refused treatment of any sort. Under the heading of palliative treatment are grouped those cases in which the patients received small doses of deep X ray colostomy for intestinal obstruction due to the presence of the tumor or other treatment instituted only with the idea of symptomatic relief and not expected to lead to cure or to appreciable amelioration of the disease. It is rather striking evidence of the delay in seeking treatment that 23 of these patients were found 17 per cent of the total.

Of course many additional patients given intensive treatment had well advanced growths when treated. Thus Leland found among 711 traced cases of cancer of the cervix treated with radium at the Huntington Hospital that only about 10 per cent fell in Class A and

Class B the 2 reasonably favorable for treatment. The table reflects the predominant use of radiation for cancer of the cervix in this vicinity.

Under the heading 'combined treatment' are included those cases in which the patients received radon and X ray treatment or radon application operation and X ray treatment. There are 32 in this group. Two cases received X ray therapy only.

Of considerable interest is the variation in the total duration of the various forms of cervical cancers. Thus the average duration of the low grade epidermoid carcinomas (2.3 years) is twice that of the high grade and half again that of the cases of medium malignancy. It must be emphasized of course that these cases are all autopsies and, therefore represent failures in treatment.

Evidence of the close correlation between the histological grade of the tumor and the distribution of metastases is further strengthened by the present study (Table II). One hundred and two of these 132 cases were pre-

TABLE III—DEGREE OF MALIGNANCY AND NUMBER OF SITES OF METASTASES

Grade	Cases	Number of sites of metastases
Epidermoid I	25	10
Epidermoid II	66	124
Epidermoid III	31	68
Grade not stated	4	0
Adeno-acanthoma	5	10
Adenocarcinoma	11	22

TABLE IV—SITES OF METASTASES

Type		Regional nodes	Distant nodes	Adrenal	Bladder	Bone	Diaphragm	Gall bladder	Heart	Kidney	Lung	Liver	Long	Ovary	Pancreas	Peritoneum	Pituitary	Spleen	Stomach	Thyroid
Epidermoid I	Before treatment	7																		
	After treatment	3	3																	
Epidermoid II	Before treatment											4								
	After treatment												4			3				
Epidermoid III	Before treatment											2	3							
	After treatment	3	3										4							
Adeno acanthoma	Before treatment																			
	After treatment	3																		
Adenocarcinoma	Before treatment																			
	After treatment	1														3				
Total	Before treatment	18	34	3		3						10				3				
	After treatment	16	27									10				8				

vously reported (2) with particular attention to the relation of grading to power of metastasis.

These consistent results are due in part to the fact that the estimation of the grade of malignancy in an autopsy is not restricted to a single small biopsy but an adequate amount of tissue is available for examination. In this way a far more accurate determination of the grade is possible. Where there is marked variation in the histological appearance of a given tumor the less differentiated two-fifths of the portion studied has been used to determine the grade.

Too much stress can not be laid on the point that histological grading is of but little value in estimating individual prognosis. Here such factors as the extent of the local lesion, the presence of metastases, the age of the patient, the type of treatment utilized, must be given due weight. However histological grading is of great value in determining the radiosensitivity of the tumor and in determining whether or not the tumor is likely to metastasize.

In this connection it might be well to emphasize that there is much confusion between

radiosensitivity and what we might term radio-curability. In general the more rapidly growing more anaplastic, more malignant tumors are sensitive to radiation and not infrequently the local growth is destroyed by the treatment. However by virtue of their tendency to wide and early metastasis and deep local infiltration in the long run these highly malignant tumors very frequently prove as unsatisfactory when treated by radium as by any other means. The difficulty, however, lies not in the failure of radiation to affect these radiosensitive tumors but rather in the failure of the field of effective radiation to include all of the malignant cells.

In the present paper we are chiefly concerned with the distribution of metastases. This distribution is summarized in Table II and the close relationship between power of metastasis and histological grade of the tumor is brought out with extraordinary clarity. The percentage of variation in involvement of regional and distant lymph nodes and other organs by the different grades of tumors is shown in the figure, which presents graphically a portion of the material in Table II.

There is also close parallelism between the degree of malignancy and the total number of sites¹ of metastasis of the tumors of a given grade. This is brought out in Table III.

Thus the highly malignant epidermoid carcinomata average over three different sites of metastasis apiece whereas those of low malignancy average less than one apiece.

In grade III epidermoid carcinoma such unusual sites as the heart, spleen, kidney and thyroid have shown metastatic involvement.

Metastasis to bone is unusual in cervical cancers but in this series it occurred five times twice in grade III tumors and three times in grade II. The metastases were all of the osteoclastic type.

A given group of nodes, as the sacral, is considered as a single site even though several nodes may be involved.

Table IV gives the detailed sites of metastases of the various types of cancers together with an attempt to differentiate those metastases present before and those after treatment.

By careful study of the clinical record combined with study of the pathological processes themselves I have attempted roughly to estimate the time at which various metastases appear. Eighty per cent of those occurring after treatment appeared within 1 year. Of course, the length of life after treatment in most cases was short.

THE FATE OF THE SIDETRACKED LOOP OF ILEUM FOLLOWING LATERAL ANASTOMOSIS FOR COMPLETE BENIGN OBSTRUCTION

A CLINICAL EXPERIMENTAL STUDY¹

C. E. HOLM, M.D., M.M.Sc., ALLENTOWN, PENNSYLVANIA

FOLLOWING a simple lateral ileo-ileostomy or ileocolostomy for complete benign obstruction of the terminal ileum the loop of ileum between the anastomosis and the obstruction may give rise to serious trouble as evidenced by the following case reports reviewed at the suggestion of Dr W. L. Estes, Jr. made to me while serving as resident surgeon at St. Luke's Hospital Bethlehem Pennsylvania

CASE 1: F. B. male aged 22 years, was admitted to St. Luke's Hospital, June 22, 1929. Three days before admission the patient was seized with acute appendicitis, and at operation—1 hour after admission—a gangrenous, perforated appendix was found within a large abscess walled off by intestinal coils. Appendectomy was done and the abdominal cavity drained. Convalescence was prolonged because of wound infection, but was otherwise uneventful. At a follow up examination on October 17, 1929 the patient was in excellent health. He remained free from abdominal symptoms until April 5, 1930 when intestinal obstruction occurred. Following his readmission to the hospital on April 7 repeated enemata failed to give relief and an operation was performed 3 hours later. The terminal 3 feet of ileum was adherent to itself, to the cecum, and to the anterior abdominal wall. Adhesions were divided to release a 3 inch loop of strangulated but viable ileum. Inasmuch as adhesions threatened future strangulation, a lateral anastomosis was established between the transverse colon and the ileum at a point 3 feet proximal to the cecum.

Throughout the convalescent period the patient had a good appetite and his general condition was excellent. A mild, painless diarrhea with considerable borborygmus and moderate distention of the lower abdomen developed 1 week before his discharge on April 22 continued in a mild form until May 4 when the diarrhea became severe, and vomiting occurred 3 days later. These symptoms became progressively worse and at admission to the hospital on May 9 the patient was found to be undernourished, dehydrated, drowsy and very toxic. The abdomen was moderately distended and generally tender but there was neither rigidity nor palpable mass. At operation the following morning the terminal 3 feet of ileum sidetracked on April 7 was found elongated to 7 feet, greatly dilated acutely inflamed and ulcerated, with the distal 1 foot completely obstructed in a mass of adhesions. The

meso-ileum contained many lymph nodes varying in size from a pea to a walnut. The colon was collapsed proximal and distal to the anastomosis. The sidetracked loop was resected, from the anastomosis to the cecum. During the manipulations of resection, several ulcerations of the loop perforated. The abdominal cavity was drained. A serious wound infection and a continuance of the pre-operative debility prolonged the convalescence. A mild diarrhea persisted throughout the patient's stay in the hospital and continued for several months after his discharge. Recuperation was slow for several months following his return home, but at the last follow-up examination in May 1931, he had gained 25 pounds in weight and his general health was excellent.

CASE 2: S. D. a boy of 16 years, was admitted to the hospital November 18, 1928 with symptoms and signs of acute intestinal obstruction of 2 days duration. At operation several loops of terminal ileum were found matted together and adherent to the lateral wall of the pelvis, around a gangrenous Meckel's diverticulum. The ileum was completely obstructed at a point near the cecum. The involved loops of ileum were resected, following which a lateral anastomosis was performed between the ascending colon and the ileum 8 inches proximal to the resection. The 8 inch limb of ileum distal to the anastomosis was placed over a large defect in the posterior parietal peritoneum. The abdomen was closed with drainage. Ten days after operation the patient became slightly distended, and began having mild attacks of visible peristalsis which recurred during the remainder of his stay in the hospital. His general condition was good. After going home on December 7, 1928 visible peristalsis recurred with increasing frequency and was associated with marked borborygmus and pain. He had from two to six loose bowel movements daily. His symptoms becoming progressively worse he was readmitted on January 26, 1929, and was operated upon 3 days later. The 8 inches of blind ileum distal to the anastomosis performed the previous November had become greatly elongated and distended and it filled the lower half of the abdominal cavity. It was coiled upon itself, with dense adhesions to the cecum and pelvic wall. The blind end of the ileum was partially freed from adhesions when the patient's general condition became too serious to permit resection and the operation was hastily terminated by performing a lateral ileo-ileostomy between a point near the end of the blind limb and an area immediately distal to the former ileocolostomy. Recovery was prompt and the patient was discharged on February 9.

Fig. 1. Roentgenographic evidence of a dilated intestinal loop noted 7 weeks following lateral anastomosis between ileum and colon.

Fig. 2. Photograph showing dilatation and elongation of sidetracked ileal loop following the operation of lateral

ileocolostomy for the relief of complete obstruction of terminal ileum.

Fig. 3. Diagram explaining photograph in Figure 2. A, Anastomosis. C, colon. I, ileum. O, obstruction. SL, sidetracked loop.

At a follow-up examination on September 21, 1929, the patient was much underweight due to a severe diarrhoea of 4 months' duration. There had been occasional attacks of distention, borborygmus and painful peristalsis. He was placed on a strict diet and on January 2, 1930, was greatly improved although abdominal distention and a mild diarrhoea had persisted. His appetite had been good through out.

The patient was readmitted on January 7, 1930, during an aggravation of the abdominal symptoms and he was operated on 3 days later. The lower two-thirds of the abdominal cavity was filled with the further elongated and dilated blind loop of terminal ileum. Proximal to the ileocolostomy the ileum seemed normal. The blind loop of ileum was freed of adhesions and resected at a point close to the ileocolostomy and the sigmoid was sutured over the denuded areas. The patient was discharged on January 18, greatly improved although he had a mild diarrhoea. The diarrhoea persisted for several weeks after his return home. At the final follow-up examination on May 8, 1931, the patient was in excellent health.

A search of the literature on intestinal obstruction disclosed only an occasional clinical reference to complications occurring in the sidetracked loop of ileum following a lateral anastomosis for complete obstruction which necessitated secondary operation and resection, and failed to reveal reports of experimental work on this problem. In order to determine the fate of the sidetracked loop after lateral ileo-ileostomy or ileocolostomy for an induced, complete and permanent obstruction of the terminal ileum, 7 dogs were operated upon. After operation all of the dogs were fed a liquid diet for 4 days, a soft diet for 3 to 4 weeks and thereafter a general diet. Fluoroscopic studies of the intestinal tract were made on 5 dogs several weeks after operation to ascertain without sacrificing the animals if dilatation of the sidetracked loops had occurred.

THE FATE OF THE SIDETRACKED LOOP OF ILEUM FOLLOWING LATERAL ANASTOMOSIS FOR COMPLETE, BENIGN OBSTRUCTION

A CLINICAL EXPERIMENTAL STUDY¹

C. E. HOLM, M.D. M.M.Sc., ALLENTOWN, PENNSYLVANIA

FOLLOWING a simple lateral ileo-ileostomy or ileocolostomy for complete benign obstruction of the terminal ileum the loop of ileum between the anastomosis and the obstruction may give rise to serious trouble as evidenced by the following case reports reviewed at the suggestion of Dr W. L. Estes, Jr. made to me while serving as resident surgeon at St. Luke's Hospital, Bethlehem Pennsylvania.

CASE 1: F. B. male aged 12 years, was admitted to St. Luke's Hospital, June 11, 1929. Three days before admission the patient was seized with acute appendicitis, and at operation—1 hour after admission—a gangrenous, perforated appendix was found within a large abscess walled off by intestinal coils. Appendectomy was done and the abdominal cavity drained. Convalescence was prolonged because of wound infection, but was otherwise uneventful. At a follow up examination on October 17, 1929, the patient was in excellent health. He remained free from abdominal symptoms until April 5, 1930 when intestinal obstruction occurred. Following his readmission to the hospital on April 7 repeated enemas failed to give relief and an operation was performed 3 hours later. The terminal 3 feet of ileum was adherent to itself, to the cecum, and to the anterior abdominal wall. Adhesions were divided to release a 3 inch loop of strangulated but viable ileum. Inasmuch as adhesions threatened future strangulation a lateral anastomosis was established between the transverse colon and the ileum at a point 3 feet proximal to the cecum.

Throughout the convalescent period the patient had a good appetite and his general condition was excellent. A mild, painless diarrhea with considerable borborygmi and moderate distention of the lower abdomen developed 1 week before his discharge on April 22 continued in a mild form until May 4 when the diarrhea became severe, and vomiting occurred 2 days later. These symptoms became progressively worse and at admission to the hospital on May 9 the patient was found to be undernourished, dehydrated, drowsy and very toxic. The abdomen was moderately distended and generally tender but there was neither rigidity nor palpable mass. At operation the following morning the terminal 3 feet of ileum sidetracked on April 7 was found elongated to 7 feet, greatly dilated, acutely inflamed and ulcerated with the distal 1 foot completely obstructed in a mass of adhesions. The

meso-ileum contained many lymph nodes varying in size from a pea to a walnut. The colon was collapsed proximal and distal to the anastomosis. The sidetracked loop was resected, from the anastomosis to the cecum. During the manipulations of resection several ulcerations of the loop perforated. The abdominal cavity was drained. A serious wound infection and a continuance of the preoperative debility prolonged the convalescence. A mild diarrhea persisted throughout the patient's stay in the hospital and continued for several months after his discharge. Recuperation was slow for several months following his return home but at the last follow-up examination in May, 1931, he had gained 25 pounds in weight and his general health was excellent.

CASE 2: S. D., a boy of 16 years, was admitted to the hospital November 18, 1928 with symptoms and signs of acute intestinal obstruction of 3 days duration. At operation several loops of terminal ileum were found matted together and adherent to the lateral wall of the pelvis, around a gangrenous Meckel's diverticulum. The ileum was completely obstructed at a point near the cecum. The involved loops of ileum were resected, following which a lateral anastomosis was performed between the ascending colon, and the ileum 8 inches proximal to the resection. The 8 inch limb of ileum distal to the anastomosis was placed over a large defect in the posterior parietal peritoneum. The abdomen was closed with drainage. Ten days after operation the patient became slightly distended and began having mild attacks of visible peristalsis which recurred during the remainder of his stay in the hospital. His general condition was good. After going home on December 7, 1928 visible peristalsis recurred with increasing frequency and was associated with marked borborygmi and pain. He had from two to six loose bowel movements daily. His symptoms becoming progressively worse he was readmitted on January 16, 1929, and was operated upon 3 days later. The 8 inches of blind ileum distal to the anastomosis performed the previous November had become greatly elongated and distended, and it filled the lower half of the abdominal cavity. It was coiled upon itself, with dense adhesions to the cecum and pelvic wall. The blind end of the ileum was partially freed from adhesions when the patient's general condition became too serious to permit resection and the operation was hastily terminated by performing a lateral ileo-ileostomy between a point near the end of the blind limb and an area immediately distal to the former ileocolostomy. Recovery was prompt and the patient was discharged on February 9.

replaced by an ulcerative process made up mainly of plasma cells and fibroblasts and other areas of small round cell infiltration extending well into the muscular layer. Sections from a grossly normal portion of the sidetracked loop disclosed hypertrophy of the muscular layer and marked swelling of the mucosa with diffuse small round cell infiltration, lymphocytes and plasma cells predominating. Proximal to the anastomosis, the mucosa exhibited a mild degeneration and small round cell infiltration while the muscular coat was extremely thin with considerable round cell infiltration, polymorphonuclear leucocytes in the minority. The macroscopically normal colon exhibited a complete loss of the staining quality of nuclei of mucosal cells. The liver showed widespread cloudy swelling and parenchymatous degeneration most pronounced around the central portion of the lobules. The kidney exhibited considerable vascular injection and severe glomerular and tubular degeneration with areas of small round cell interstitial infiltration.

Dog 499. An ileal obstruction was produced 6 inches from the cecum and a lateral ileo-ileostomy was established between points of the ileum 16 inches proximal 3 inches distal to the obstruction.

The immediate postoperative recovery was un-

important and the dog remained well and active for 5 weeks, when diarrhea developed and became increasingly more severe with slight distention and borborygmus. He lost weight but remained active and bright. Fluoroscopic examinations 6 and 7 weeks after operation demonstrated hyperactive peristalsis and a dilated loop of intestine. Roentgenogram is shown in Figure 4. Symptoms did not change during the following 7 weeks, except for lassitude and continued weight loss. The dog was sacrificed 14 weeks and 5 days after operation.

At autopsy the anastomosis was firmly healed around a stoma about 2 inches in length. The sidetracked loop of ileum had elongated from 16 inches to 38 inches and the terminal 8 to 9 inches had dilated to about four times the normal diameter. The walls were very thin in many areas, although the terminal 4 or 5 inches seemed to be hypertrophied. There was slight dilatation of the ileum for 1 inch beyond the obstruction. The colon and the ileum proximal to the anastomosis seemed normal. There were many large lymph nodes in the meso-ileum. The intestines were photographed (Figs 5 and 6), and then placed in formalin solution. Sections of normal appearing tissue were removed from the right lobe of the liver and the right kidney.

When the specimen was opened the terminal 5 inches of the dilated loop were found definitely hypertrophied with scattered ulcerations.

The 8 inches proximal to this were thin walled with many deep ulcerations. There were scattered ulcers in the remainder of the loop and distal to the obstruction. The colon and the remainder of the ileum seemed normal.

In a microscopical section taken from the hypertrophied portion of the dilated loop the muscle layer was greatly thickened with a degeneration of muscle fibers many of which were displaced by inflammatory tissue. The mucosa was markedly degenerated, necrosed, and infiltrated with inflammatory cells. The ileum 10 inches proximal to the anastomosis manifested slight degeneration of the mucosa and muscular layers. The liver exhibited widespread and intense fatty infiltration with pigmentation of the liver cells, most pronounced around the central veins. There was vascular congestion and some of the central veins had thickened walls, while others were occluded with blood cells nodding organization. The kidney showed advanced tubular and moderate glomerular degeneration.

Dog 65. The operative procedures on this dog were designed to simulate those in Clinical Case 3.

The ileum was severed transversely 6 inches from the ileocecal juncture and its ends were turned in. A lateral ileo-ileostomy was performed allowing the proximal end of the ileum to extend 8 inches beyond the anastomosis.

The immediate postoperative recovery was uneventful. Diarrhea developed in 3 weeks and became increasingly more severe. There was listless ness, slight distention and considerable weight loss at the end of 6 weeks. The fluoroscope demonstrated a dilated loop 6 weeks after operation. A roentgenogram was made (Fig. 7). The condition of the dog remained unchanged during the next 4 weeks and he was sacrificed 10 weeks and 3 days after operation. The appetite was well maintained throughout.

At autopsy, performed very soon after death there was no evidence of peritonitis, the anastomosis was well healed, and the stoma was 1½ inches in diameter. The blind limb of ileum had elongated from 8 to 16 inches and the terminal 8 inches had dilated to three times the normal caliber with the walls generally thin (Figs. 8 and 9). The lymph nodes in the meso-ileum were greatly enlarged. The section was removed and placed in formalin solution. Seemingly normal tissue was removed from the right lobe of the liver and from the right kidney.

When the specimen had been opened the terminal 4 inches of the dilated limb were found hypertrophied with many small ulcerations. The walls in the remainder of the loop were thin and ulcerated. There were scattered ulcerations in the ileum proximal to the anastomosis, between the anastomosis and the cecum, and in the colon.

Microscopically a section from a thin portion of the dilated limb manifested marked degeneration

and necrosis of the mucosa extending to the muscle layer. A section from a thick portion of the limb displayed degeneration and necrosis of the surface of the mucosa. Sections from normal appearing colon, showed small round cell infiltration and slight degeneration of the mucosa. The liver and the kidney exhibited the same type of widespread degenerative changes seen in the other dogs.

Dog 487. Obstruction was produced and an ileo-cecostomy was established as in dog 575. The immediate postoperative course was similar to those described in the protocols of the other dogs. Death occurred 6½ weeks after operation from general peritonitis, due to a perforation in the obstructed loop. Gross and microscopical findings were much the same as those described in the three protocols. The terminal 3 inches of the sidetracked loop were hypertrophied.

Dog 651. Operative procedures were the same as in dogs 575 and 487. Postoperative symptoms and physical findings were almost identical to those previously described. A dilated loop of intestine was observed fluoroscopically after a barium meal at the end of 5 weeks. The dog was sacrificed during the ninth week. Macroscopically and microscopically the findings were similar to those in the other dogs.

Dog 713. Obstruction and ileo-ileostomy was done as in dog 490. The postoperative course was practically the same as that of all the other dogs until death occurred 6 weeks after operation from general peritonitis resulting from a perforation in the obstructed loop. Gross and microscopic findings were similar to those found in the other dogs. The terminal 1½ inches of the obstructed loop was hypertrophied.

Dog 493. A lateral ileo-ileostomy was performed as in dog 657 leaving a blind limb 6 inches long. The postoperative course was about the same as that of the other animals. Fluoroscopic evidence of a dilated intestinal limb was seen at the end of 7 weeks. It was necessary to sacrifice the animal 13 weeks after operation because of extreme emaciation and debility. The terminal 5 inches of the enlarged blind limb were hypertrophied. Macroscopic and microscopic findings were similar to those observed in the other animals, but in all instances the degenerative changes were more advanced.

SUMMARY

In two clinical cases of complete obstruction in the terminal ileum resulting from adhesions, various types of lateral anastomoses were done without removal of the ileum between the anastomosis and the obstruction. Following the anastomoses the patients developed diarrhea, borborygmi, abdominal distention, marked weight loss and debility without impairment of appetite. In each

patient complete recovery followed resection of the sidetracked loop, which was greatly elongated, markedly dilated, and ulcerated.

An intestinal obstruction was produced in the terminal ileum in 7 dogs, following which various types of lateral anastomoses were done, allowing the sidetracked loops to remain. After operation all of the dogs developed diarrhoea, borborygmus, distention, weight loss and debility, but maintained a good appetite. Two dogs died from general peritonitis resulting from perforation of the sidetracked loop. Five dogs were sacrificed. In all 7 dogs the sidetracked loop was found markedly elongated, greatly dilated and ulcerated. Microscopic sections showed areas of deep and superficial ulceration in the dilated loops, superficial mucosal ulceration of the ileum and colon remote from the sidetracked loops, and widespread advanced degenerative changes in liver and kidney.

CLINICAL APPLICATION OF EXPERIMENT

The terminal ileum was selected for study in the experimental work because it is a common site for obstruction from adhesions as evidenced by the two clinical cases.

Photographs of roentgenograms and dilated sidetracked loops displayed on the abdomens of the dogs have been omitted in the abstracts of the four protocols because they were practically identical to those presented.

The more advanced liver and kidney changes in two dogs might have been due, in part, to the general peritonitis.

The superficial necrosis of the mucosa in the intestines remote from the sidetracked loop, indicated a general enterocolitis as the cause of the severe diarrhoea in all of the animals. It is assumed that a similar condition existed in the two clinical cases reported and was responsible for the diarrhoea which persisted throughout their illnesses and for several months after resection of the sidetracked loops.

The type of degenerative changes observed in the liver and kidney sections from the dogs probably were present in the 2 patients and might have been a factor in the toxicity which they displayed and the period of slow recuperation which followed resection.

The postoperative signs and symptoms occurring in all of the dogs were similar to those observed in the two patients prior to resection of the sidetracked loop.

Fluoroscopic and X-ray examination aid diagnosis in detecting elongation and dilatation of the sidetracked loop of ileum in patients who exhibit the symptoms and signs of the two clinical cases.

Surgeons generally recognize that it is not advisable to permit a blind limb to extend beyond a side-to-side anastomosis. In any lateral anastomosis for permanent, complete obstruction the sidetracked loop corresponds to a blind limb extending beyond the anastomosis.

CONCLUSIONS

1. The sidetracked ileal loop of a lateral ileo-ileostomy or ileocolostomy for complete benign obstruction of the terminal ileum is likely to become greatly elongated, dilated, and ulcerated. An enterocolitis with mucosal degeneration and degenerative lesions of the liver and kidneys will probably develop.

2. Whenever possible the sidetracked ileum should be resected at the time the lateral anastomosis is done.

3. If resection is inadvisable because of the condition of the patient, the lateral anastomosis should be done as near the obstruction as possible, and should be regarded only as a first stage operation, to be followed by a resection of the sidetracked loop of ileum at a more favorable time.

4. As an alternative procedure it is suggested that the ileum might be divided as close to the obstructive lesion as possible and be followed by an end-to-side anastomosis which eliminates a blind end.

LIGHT AND TAR CANCER

AN EXPERIMENTAL STUDY WITH A CRITICAL REVIEW OF THE LITERATURE ON LIGHT AS A CARCINOGENIC FACTOR

M. G. SEELIG, M.D., F.A.C.S. AND ZOLA K. COOPER, Ph.D. ST. LOUIS, MISSOURI
 From the Research Laboratory of The Bernard Free Skin and Cancer Hospital

PART I. EXPERIMENTAL STUDY

DESPITE the fact that the rôle of light in the genesis and development of cancer is of interest both experimentally and clinically, very little clear-cut experimental work has been done upon this subject. Part II of this paper, a critical review of the literature on light as a carcinogenic factor, emphasizes the necessity for well controlled experimental data. With the object of collecting such data, we attempted to determine the carcinogenic effect of tar applied to mice kept in an environment from which light was totally excluded.

Material and methods: In one corner of our animal room, a light proof chamber 18 by 15 by 12 feet was built two sides of which were made up of the south and east walls of the animal room, and the other two sides of 0.5 inch fiber board (Masonite) that extended from floor to ceiling. There were three windows in the original wall space. Instead of walling in these windows light traps were built about them so as to permit the entrance of air and to exclude light. The entrance to the room was through a light proof maze built of fiber board. All joints and crevices in the fiber board walls were made light proof by caulking. A 14 inch galvanized iron flue pipe painted black on the inside and furnished with light blocking baffles entered through a light tight opening and led to an exhaust fan within the dark room. In this manner a constant stream of fresh air was kept moving from the windows out through the exhaust duct. In the room were two steam radiators, by means of which the temperature could be regulated. The room was furnished with racks for mice cages, a work bench provided with a ruby light and storage places for animal food¹ tar

and various accessories. This room assured total darkness and an environment that was otherwise comparable to that in which mice live out their natural lives in the ordinary well constructed animal room. After the room was built a set of highly sensitive photographic plates were exposed in it for 48 hours. When developed these plates showed no evidence of being light struck.

The tar used in these experiments was distilled so that only the fraction coming off at 370 to 440 degrees C. was collected. This distillation² was so executed that this tar fraction (370 to 440 degrees C.) was not exposed to light during the process. The tar was then kept stored in the dark room, in light proof receptacles.

Three sets of mice were segregated for the experiment. (1) 125 male mice, approximately 3 months old, were set apart for tarring in the dark. (2) a similar group of 125 were set apart for tarring in the light and (3) a similar group of 50 were kept as controls in the dark room. This last group was not tarred and was used merely as a check on living conditions in the dark. The experiment was not begun until the mice had been kept in the dark for 3 weeks.

After the elapse of this preliminary period the group of 125 mice kept in the dark were tarred as were the similar group kept in the light. After preliminary depilation with sodium sulphide, tar was applied between the scapulae once or twice a week until the animals died. A complete autopsy was performed on every mouse. All skin lesions and all suspicious visceral nodules were removed and examined in microscopic sections.

It was not until the experiment had run almost 4 months that we fully realized the advisability of using genetically bred mice. The comments of Little have much force, even

¹As an added precaution, the animal feed (chiefly cracked corn) was kept in the dark room. The green stuff and bread and milk, which were necessary in the diet of the mice, could not be kept entirely unexposed to light.

²W. are indebted to Messrs. D. Wilson and J. Kohlberg, of the Lacerte Gas Light Company of St. Louis, for their co-operation and assistance in the operation of the distillation on our behalf.

though one may not be willing to subscribe unqualifiedly to his statement that it is to day as careless to use unknown genetic material in experimental pathology as it is for a chemist to attempt to analyze substances using unknown rather than known reagents." After much soul searching we decided to present our data such as it was, rather than to start the long drawn out procedure of raising 300 genetically bred mice, and starting the experiment anew. We were emboldened in this position by the fact, as emphasized by Roffo, that in tar cancer, the receptivity or susceptibility varies not only in animals of different species and in animals of near relationship but even among animals of the same family. Moreover susceptibility varies in different anatomical sites of the same animal and possibly even in cells of the same anatomical site. Twort and Twort emphasize in particular the impossibility of establishing a standard value of the unit of carcinogenicity. Reinhard and Candee found that strains of mice with either a high or low incidence of spontaneous cancer responded similarly to tarring except that the latent period in the low incidence strain was 14 weeks longer than in the high. Parodi found also that individual susceptibility varied even in a strain of genetically bred mice. These several observations in addition to Roffo's testimony strengthened us in our determination to run the experiment through with ordinary laboratory mice.

**GROUP I 125 MICE TARRIED 23 TIMES DURING
A PERIOD OF RESIDENCE IN TOTAL DARK
NESS OF 27 WEEKS**

After living for 3 weeks in the dark the mice of this group were tarred with the high fraction tar distillate, already mentioned. The tar was applied to the interscapular region at the root of the neck over an area about 1.5 centimeters in diameter. At first these applications were made every third day but our tar proved to be so highly toxic that we varied the time interval between paintings to meet the problem of high death rate. The last animal in the group died 24 weeks after the first application of tar and during this period tar was applied 23 times. During the last 4 weeks

of the experiment no application of tar was made. In the early part of the experiment crust was removed as it formed at the site of application of the tar but since this seemed to favor toxic absorption of the tar we, later let the crust drop off spontaneously.

When an animal died a complete autopsy was performed, the tarred area was excised and paraffin sections of it prepared. From the outset we determined to call only those growths carcinomata in which we could demonstrate that the neoplastic epithelium infiltrated the subcutaneous muscle layers. It scarcely seems advisable in this report to go into the lengthy and intricate chapter of the essential histological criteria of tar cancer. Those who are interested will find the subject discussed by Woglom and by Seelig and Cooper. Here it suffices to say that intramuscular infiltration seemed to us to be of all others, the most satisfactory and reliable basis for the diagnosis of cancer. We avoid the use of the terms epithelioma and canceroid and, although in several of our mice (in the group kept in the dark and likewise in the group kept in the light), the cell morphology, growth tinctorial reaction, and mitotic activity of the lesions, pointed indubitably to the diagnosis of cancer we did not record the tumor as such unless it infiltrated out of bounds into muscle tissue.

In Group I, thickening and keratosis of the skin was noticeable macroscopically 2 weeks after the first application of tar. At about 8 weeks after the first painting papillomata began to appear. Some of these growths which macroscopically appeared to be papillomata proved microscopically to be more on the order of keratotic warts. After 4 weeks of tarring 27 mice had died, a mortality rate of slightly over 20 per cent. Part of this high mortality rate (which was paralleled by the control group tarred in the light) was due to toxic effects of the tar and part of it to an epidemic of diarrhoea, which invaded the entire colony of laboratory at this time. Later our animals suffered from what seemed to be an epidemic form of pneumonia. However the death rate among the animals used in this experiment was not high enough to invalidate our final results.

Beginning with the eighth week papillomata were abundant and from then on these papillomata either showed a tendency to develop induration about the base, or to ulcerate. Some of them dropped off to be replaced by new papillomata.

By the end of the eighth week approximately 50 per cent of the animals had died by the end of the twelfth week, 70 per cent by the end of the twentieth week, 90 per cent. There were now 8 surviving animals which succumbed one by one, the last one dying 24 weeks after the beginning of tarring. An analysis of this mortality rate discloses that if we assume dogmatically that we might expect carcinogenesis to develop about the tenth week then at this time 47 of our original group of 125 mice remained alive. Of these 47 mice that remained 11 mice developed carcinomata, conforming to the histological criteria already described. The tumors were all of the squamous cell type, and all of them presented histological evidences of very active growth (mitoses markedly anaplastic cells,—both with regard to size and shape of the cells and variations in tinctorial reaction—and very little evidence of keratinization or pearl formation).

Visceral metastases were found in only 3 of the 125 mice in Group I. These 2 animals showed squamous cell carcinomata of the lungs. In one mouse, a regional lymph node of the root of the neck showed a metastatic squamous cell carcinoma. (In the case of the lymph node, it was quite apparent that we were dealing with a metastatic focus but we are unwilling to dogmatize regarding the carcinomatous foci in the lung for we know of no reliable method of differentiating primary or spontaneous carcinomata of the lungs from secondary or metastatic foci).

The 11 mice that developed carcinomata died 110 116 125 136 139 146 147 150 153 155 and 157 days, respectively after the beginning of tarring. In view of the fact that our plan was to examine tissues only after the animals had lived out their lives and that we were unwilling to add the element of trauma, incident to performing a biopsy we cannot furnish data regarding the earliest time at which the cancers were demonstrable. The

most that we can say is that 11 out of a series of 125 mice developed cancer (approximately 9 per cent) and that the average duration of life of these mice was 140 days after the beginning of tarring.

In Group I 2 mice developed growths that showed all the other characteristics of malignancy but that did not infiltrate muscle. We did not classify these tumors as malignant.

GROUP II 125 MICE, TARRIED 27 TIMES DURING A PERIOD OF RESIDENCE IN THE LIGHT OF 32 WEEKS

In this control group as in Group I, we found that owing to the toxicity of our tar we could not make the applications on fixed dates or at predetermined intervals. The last animal in this group died 32 weeks after tarring was begun and during this period, tar was applied 27 times. It will be noted, therefore that the length of the experiment was 5 weeks greater than that of Group I and that 4 more applications of tar were made. It scarcely seems warrantable from these facts to draw any specific conclusions regarding the influence of light on the general hygiene and duration of life of the animals or on the toxicity of tar.

In this group just as in Group I each animal was permitted to live out its life pathological examinations being made in every instance after death. Macroscopically no essential differences from Group I were apparent in this group with regard to crusty thickening of the skin, keratosis or development of papillomata. At the end of the sixteenth week the mortality rate was 85 per cent, as contrasted with 84 per cent in Group I by the end of the twentieth week the mortality was 90 per cent as contrasted with 88 per cent in Group I. The last animal died 228 days after the tarring was begun. A particularly interesting phase of the comparative mortality rate in the two groups is that the early mortality was much greater among the animals of Group I. For example at the end of 4 weeks the mortality rate in Group I was 23 per cent, whereas in Group II it was 9 per cent (see Table I).

The significance of this difference in mortality rate lies in the fact that a larger number

of mice in Group II received applications of tar over a longer period of time than in Group I. Despite this in Group II only 5 carcinomata developed as contrasted with 11 that developed in Group I. In all of the animals the tumors were of the same histological type as those in Group I and in one animal there developed a squamous cell carcinoma of the lung which we considered metastatic. In this group the first animal in which carcinoma was found died 161 days after painting began the other 4 animals dying respectively 172, 194, 198 and 221 days after the beginning of painting. Compared with Group I these figures would seem to indicate a delayed effect but since we had no way of determining exactly when the cancers developed we do not feel warranted in stressing the time element.

In this group there were 3 mice with tumors that showed all the other characteristics of malignancy but that did not infiltrate muscle. We did not classify these tumors as carcinomata.

GROUP III 50 MICE UNTARRED KEPT IN THE DARK FOR 22 WEEKS

This group was used merely to check the effect of living conditions in the dark room. An unusually high mortality rate might have indicated that darkness alone exercises a marked constitutional effect on the animals. However, when the last of the tarred animals died in the dark, 21 of the original 50 of the untarred animals of Group III were still living. This represents a mortality rate of 58 per cent which is not abnormally high for a group of 50 mice over a period of 22 weeks. If we bear in mind the two epidemics already mentioned, it would seem therefore that complete darkness in itself does not influence the general condition nor the mortality rate of the mice to a degree that in any way affects the experiment.

CONCLUSIONS

1. The absence of light did not cause any physical compromise in a group of mice subjected to total darkness over a period of approximately 5 months.

2. White light is not a necessary factor in the development of tar cancer in mice, be-

TABLE I—MORTALITY RATES

	Group I Tarred in the dark	Group II Tarred in the light	Group III Not tarred in the dark
Number of mice	5	5	5

Experiment discontinued after 22nd week—4 per cent of animals still living and well.

cause in total darkness in the group of mice used in these experiments a larger number of tar cancers developed than developed in a similar group of mice that were tarred and kept in the light.

3. The comparatively larger number of carcinomata occurring in the mice kept in the dark is too small to warrant the conclusion that the absence of light in itself favors the development of tar cancer in mice.

4. These experiments do not eliminate the possibility that light may be a secondary factor in the genesis of experimental cancer. They furthermore do not warrant dogmatic and direct deductions applicable to human cancer.

PART II A CRITICAL REVIEW OF THE LITERATURE ON LIGHT AS A CARCINOGENIC FACTOR

Ten years before the beginning of the present century the Hamburg dermatologist Unna, made elaborate histological studies of the influence of light on the development of cancer. These studies were made in relation to the development of cancer in Xeroderma pigmentosum and in 'sailors skin' (a disease described originally by Unna). Unna

announced that light was the noxious agency in the production of these two special forms of cancer and that the histological changes to be noted in the precancerous skin lesions (capillary hyperemia, venous ectasis, hyperkeratosis, sclerosis of the skin surface and pigmentation) indicated endeavors on the part of the skin to neutralize the injurious influence of light. The pigmentation blocks all light and the hyperemia protects the deeper structures by cutting out the highly actinic blue rays (as does the photographer's ruby light). The hyperkeratosis, sclerosis and capillary strophy of the papillary bodies operate not by arresting the light but rather by diminishing its influence on cutaneous tissues that are less sensitive drier harder more tendonous and callous.

Watkins-Pitchford in 1909 attempted to develop an all embracing theory that cancer whether of special sections of community life or of special parts of the body of the individual is caused by an illumination in excess of that which can be dealt with by the protective agencies of habit posture coverings and external pigmentation and in excess of that which may be controlled by the agencies of internal pigmentation and cell memory for former-environment that the generally increased liability of man as compared with the lower mammalia is chargeable against the comparative novelty of his attitude and almost complete loss of his hairy coat that the special liability of the white man, as compared with the black man is due to the loss of pigmentation and to his changed environment and finally that these liabilities do not show themselves in the individual as vague general and constitutional predisposition but are strictly confined to those parts of the body in which irradiation becomes excessive.

Watkins-Pitchford characterizes his thirty page prize essay as purely an induction from observation. It is all of this and nothing more. The author has assembled however a striking amount of comparative anatomical, physiological pathological and ethnological data in support of an hypothesis which he leaves unproved. Hoffman suggests that the high incidence of cancer among seamen

and fishermen may lend support to Watkins-Pitchford's hypothesis. This is possibly true but a great deal of support would be necessary in order to furnish essential strength to an hypothesis that makes light the agency in the causation of cancer.

Paul states that the most important cutaneous lesions in Australia (viewed from the standpoint of prevalence and destructive effects) are rodent ulcer and epithelioma. He believes that the most significant causative factors of these lesions are the actinic rays of light, and that the most significant inhibiting factor is the pigment deposit in the skin, particularly noted in the colored races occupying the tropical and subtropical countries. In these people the effect of sunlight is minimal despite the fact that exposure to it is most severe and long continued.

Paul believes that melanin stands as a skin sentinel protecting the underlying tissues from the baneful effects of sunlight. In the white races this pigment is confined for the most part, to the periphery of the cells of the basal layer of the epidermis and the lowermost stratum of the prickle cell layer while the pigment granules may also be found in the inter epithelial spaces and in the fusiform connective tissue cells of the papillary body. Paul quotes Macleod as authority for the statement that in the dark races pigment is to be found as high up as the transitional layers of the epidermis as well as in some of the connective tissue cells of the superficial portions of the corium.

Watkins-Pitchford and Paul are not the only authors who stress the possibility of making the actinic light rays responsible for skin cancer. Duhig also thinks that they are the sole factors responsible for that disease, though he admits that the evidence on which his belief rests is indirect. Duhig is pathologist to the Coast Hospitals Board and to the Brisbane Hospital, in Queensland, Australia where he gathered the data on which he bases the following statements:

Cancer of the skin is four times more common in males than in females, and in those females affected, considerable periods of exposure to the strong sunlight of Queensland have been known to occur. Those males affected, almost invariably give a good

history of exposure. Also the disease is one preponderantly of life beyond the middle years, that is, the longer the exposure, the greater the incidence, while lack of exposure runs concurrent with the absence of the disease even in advanced life.

The disease occurs practically exclusively on those parts of the body constantly exposed to sunlight. In 3 cases only of nearly 500 investigated did cancer occur on habitually unexposed skin—once on the foot, probably as the result of trauma, once on the thigh for a similar reason, and once on the thoracic wall for no discoverable reason. The disease occurs preponderantly on the face, ears, and neck, and on the back of the hands in only about 5 per cent of the cases. Cancer of the back of the neck is almost exclusively confined to males at present, though I would predict that as a result of the fashion of short hair and the very silly use of berets and cloche and similar brimless hats in summer affected by women in this country in an effort to keep up with the overseas magazine life, cancer of that part of the body will be later just as common among women as now amongst men.

It is strange that no direct evidence of an experimental kind is available as to the effect of sunlight on the human skin, though some little work has been done on the effect of the ultraviolet and of the spectrum. I do not know that it is necessary to prove experimentally the bad effect of direct sunlight on the human skin, to me such work would only go to confirm my present opinion that *skin cancer is solely due to excessive exposure to sunlight*. It is commonly believed that only persons of ruddy complexions accompanied by russet or reddish hair are susceptible. After a long experience I would say that probably susceptibility is inversely proportional to abundance of skin pigment in a general way, but that a brunette complexion is not a safeguard. It is a very significant fact however that cancer of the skin does not occur in India, to any extent among the native races.

In an article on cancer in the negro Hoffman furnishes a veritable storehouse of information on the subject of cancer in the dark skinned races of the world. The data presented by Hoffman is so highly statistical and his reasoning so closely knit that an injustice would be done him by an attempt to abridge his article within short compass. He does however make categorical statements to the effect that (1) cancer mortality of the American negro tends more and more to approach that of the white population as the result of a persistent rise in the cancer death rate of the negro during the past 30 years, (2) negro women show a much greater liability than white women, to malignant and benign tumors of the generative organs and also of

the breast, (3) the prevailing rate of cancer of the skin is 3 times higher in whites than in negroes.

It is of course manifestly inadequate to select three terse statements such as the above from an essay packed with information, but for our immediate inquiry it is sufficient to know that Hoffman is strongly inclined to believe that available statistics seem to support the opinion that the colored races are less liable to skin cancers because of the protective influence exercised by the pigment of the skin.

Heller in his study of cancer in tar and mineral oil workers in the United States found a very low incidence of the disease. In part he attributes this to the fact that the negro workers in this industry possess at least a partial immunity to skin cancer. This assumption carried with it of necessity the conclusion that the carcinogenic effect of tar is, in part at least, dependent upon the activating influence of light.¹

In the clinic of The Barnard Free Skin and Cancer Hospital of St. Louis we have made no special survey, but it is the unanimous opinion of all the workers in this institution that although breast and visceral cancer is very common in the negro, strikingly few patients with skin cancer have been seen during the past 25 years.

Up to this point, we have considered only those investigators, who have contented themselves with formulating experimentally uncontrolled hypotheses regarding the influence of light on the development of cancer. It has, of course, been recognized for years that the carcinogenicity of actinic rays could not be accepted on any other than experimental proof. Considering the importance of light as a possible factor in cancer, one is struck by the scanty effort devoted to the experimental study of this topic.

Grynkrant makes a contribution which seems to have the flavor of research, but which in reality is only a theory built up on an intricate bit of hypothetical reasoning involving exogenous and endogenous light rays (the latter corresponding to the so called mitogen

¹Heller does not furnish any grounds for believing that the negro enjoys any other special immunity not shared by white workers.

etic rays of Gurwitsch and a hypothetical *sensibilisateur* which permits the utilization of light and puts the cell nuclei in resonance with the wave length.

Bachem and Reed developed a method of measuring the transmission of light rays through tissues, thus facilitating the study of the problem of penetration. The method depended essentially on filtering the rays of a Kromayer lamp, an incandescent bulb and infra red radiation. These authors concluded from their studies that the visible and near infra red rays are strongly absorbed in the blood of the corium and subcutaneous layers that the infra red has very little penetrating power, not much of it going beyond the epidermis and that variation in percentage penetration is greater in the ultraviolet than in other portions of the spectrum. At 280 millimicrons absorption is marked in the corneum and prickle cell layer. On both sides of the band near 300 and 250 millimicrons the penetration is greater, reaching the stratum malpighii and corium. From 250 millimicrons down the absorption is so complete as to prevent any radiation from reaching the living layers of the skin. These authors believe that the strata corneum and granulosum must play an important part in light protection in lower sensitive layers.

The lipids, and in particular cholesterol, have assumed an increasingly prominent rôle in the story of cancer genesis. Roffo who has probably done the largest amount of work in this particular field, believes that the lipids exercise a strong influence in preparing the terrain for cancer growth. More than this, he correlated the greater frequency of cancer of those regions of skin exposed to light with the increased cholesterol content of the exposed areas. Rats exposed to the sun developed a larger percentage of cholesterol than did control animals. Roffo also reports observations to prove that in cancer and precancerous lesions there is an hypercholesteremia, with localization of cancer in the regions showing highest percentages of cholesterol. He believes that a relationship exists between the photoactivity of cholesterol and cell function, that sunlight serves to fix the cholesterol in the tissues, and that cholesterol then becomes an

organic accumulator of light. The cholesterol becomes photoactive as a result of oxidation by light, the intensity of the oxidation depending upon the length of irradiation. Irradiation produces molecular changes, the molecular weights varying according to the duration of radiation.

One hesitates to accept some of Roffo's conclusions regarding the specific agency of cholesterol in cancer, and this hesitancy becomes all the more pronounced if one believes with Bishop that "our knowledge of the factors that determine the level of the various lipid constituents in the blood in disease is pitifully meager. There is no evidence to support the suggestion of abnormal cholesterol conditions in association with cancer." Any one who carefully surveys the literature of tar cancer must be struck by the conflicting reports regarding the stimulating or inhibiting effect of lanolin, whether applied at the tarred site or remote to it. These conflicting reports incline one to be skeptical of Roffo's conclusions. Downes, in a study of 63 cases of malignant tumors, could find neither a constant relationship between the concentration of cholesterol in whole blood and plasma, nor any increase above normal of the blood cholesterol in the presence of cancer. Klaus reports a lowering of blood cholesterol in genital cancers in women. Thus, the reports vary all the way from hypocholesteremia to hypercholesteremia, rendering the topic one of utter scientific chaos.

Unfortunately we encounter a somewhat similar state of affairs in the published experimental data dealing with the carcinogenic power of the ultraviolet rays of the spectrum. There seems to be no doubt that ultraviolet light is a factor in initiating skin cancers, but there is a clear cut conflict of opinion as to whether or not these rays serve to hasten the process of cancer development in mice that have been tarred.

Findlay (7) impressed by the citations in the literature of the high incidence of skin cancer in sailors, bargemen, fishermen, lightermen, farmers, gardeners, and graziers, in America, England, France, Italy and Australia, concluded that even if the statistical value of the various reports were not high,

they nevertheless suggested strongly that sun light and ultraviolet light may play an important part in the genesis of cancer

In order to check this assumption, Findlay exposed mice to the rays of a quartz mercury vapor lamp. His conclusions were (1) Exposure of mice to ultraviolet rays for a period of at least 8 months caused the development of papillomata and epitheliomata (malignant) of the skin. (2) When mice were tarred and exposed to ultraviolet light the period necessary for the induction of cancer was shorter than when either tar or violet ray exposure was used alone. (3) A series of 20 mice, tarred for one month did not develop cancer, but in a similar series tarred and exposed to ultraviolet light at the same time 3 mice developed cancers.

In a later paper Findlay reported the development of cancer in rats following exposure to ultraviolet light. The period necessary for induction of the cancers in rats was 21 months, in contrast with 8 months in mice but Findlay attributes the increased time element to the species difference rather than to the nature of the stimulus.

Herlitz, Jundell and Wahlgren exposed 27 mice to ultraviolet rays for 1 to 2 hours every 1 to 3 days for 7½ months (quartz lamp 70 centimeters distance). After 200 days 17 mice were alive and all of them showed one or more skin tumors, most of which were carcinomata. A group of control animals showed no tumors.

Putschar and Holtz exposed 57 rats, day and night, to ultraviolet rays at a distance of 60 centimeters. After a period of more than 6 months, 13 of the 35 living animals developed malignant new-growths. These authors question the accuracy of Findlay's observations because of his much shorter exposures.

Rathman and Bernardt also question Findlay's conclusions and report that using rabbits they were not able to produce experimental cancer after 9 months of daily exposure to ultraviolet rays.

Kohn Speyer reached the conclusion from her experiments that irradiating mice with ultraviolet light as an adjunct to tarring does not produce tumors (warts) more quickly than does tarring alone. She is unable to explain the discrepancy between Findlay's and

her findings but suggests that Findlay's rested on some as yet undetermined cause other than ultraviolet radiation alone.

There remains for discussion the work that has been done in natural light, in light in other than the violet end of the spectrum, and in the absence of all light. With the exception of the clinical observations of the supposed relationship between sunlight and skin cancers which we have already noted and the work of Roffo on the carcinogenic potency of photo-active cholesterol which we have also discussed, very little work has been done with pure sunlight. Neumann in an experimental study of tar cancer merely mentions the fact that animals (mice) exposed to "intense illumination" showed no greater tendency to develop malignant tumors than did those that were kept under ordinary conditions.

From what we know of the rôle that light plays in some of the diseases of metabolism, and from what we know of the clinical effects of light deprivation it is not difficult to imagine that this same agency may be a factor in the origin and growth of cancer. A recent paper by Dodds calls attention to some of the work done by Warburg illustrating by "a remarkable observation" the influence of light on the process of cell respiration. "If a slice of tissue is poisoned with carbon monoxide (CO) gas cell respiration is strongly inhibited in the dark, but reappears when the tissue is brightly illuminated."

It is of course self-evident, that one of the approaches to the problem of light as a carcinogenic agent lies in the direction of determining the effect of its total exclusion. The value of such an approach, it seems to us lies in large part in securing total darkness in the photochemical sense. Animal experimentation under such conditions is not easy of accomplishment. Marsh emphasizes this when he calls attention to inadequate ventilation and high temperature as compromising features of his experiments. Dodds (who kept his mice in individual darkened cages) reports that mice can develop tumors in darkness but by his own statements he admits that his cages were "nearly light tight" and that the darkness in the cages was "all but complete." If we are testing the effect of absence of light,

then light must be absent and not partially absent. In Part I of this paper we have described in detail how exclusion of light may be accomplished without in any other way interfering with the routine life of mice.

In addition to Dodds the following workers have studied the effect of absence of light: Bang Lipschuetz, Schorr and Ssobolewa, and Vlès, De Coulon and Ugo. Half of these workers report that complete darkness exercised no influence on the development or growth of tar cancers, whereas the other half report that darkness tends to inhibit the development of tar cancers. Bang mentions, incidentally that mice kept in complete darkness develop cancer as rapidly as do control animals. Unfortunately he furnishes no information as to what constitutes *obscurité complète* in his experiments, how many animals he used in his light experiments or what were his criteria of malignancy. The fact that in all his experiments (including the ones done in darkness) he secured 115 cancers in 263 mice arouses the suspicion that what he called cancer would not be so classified in our laboratory. Bang's work leaves a residuum of doubt on several counts, and leaves room for confirmatory work.

Lipschuetz is very definite in his statement that he worked in a well constructed photographic dark room though no mention is made of means of regulating temperature or ventilation. He found that darkness played no inhibitory rôle in the development of pigment (melanomas) in his tarred mice. But here again one is left in reasonable doubt regarding the significance of darkness in the development of tar cancer because Lipschuetz was exclusively studying pigment formation and in black and gray mice.

Schorr and Ssobolewa divided tarred white mice and mice with transplanted tumors into groups (14 to 58 mice in a group) and subjected each group to varying light conditions which were maintained during the process of tarring. They concluded from their experiments that light cannot be disregarded as a factor influencing the development of experimental cancer. Absolute darkness seemed in some instances to have no effect but as a rule darkness and also exposure to blue rays

retarded the development of cancer and also lessened the tendency of the tumors to ulcerate. In spite of repeated careful reading of the article by Schorr and Ssobolewa, we could not determine how they excluded light, nor how efficiently it was excluded.

Vlès, De Coulon and Ugo merely make the unsupported statement that when mice were kept in close confinement in dark cages, a retardation in the development of cancer in the tar painted animals occurred. Naturally one has difficulty in determining just how to evaluate such a statement.

The conclusion that one must almost inevitably draw from a survey of the literature on light as a carcinogenic factor is that more direct experimental evidence and data must be furnished if one hopes either to confirm the hypotheses that have been put forward or to evaluate the worth of conflicting conclusions that have been drawn from experimental data. With such an object in view the experiments detailed in Part I of this paper were planned and executed.

THE RESISTANCE OF HEALING WOUNDS TO INFECTION

JEAN JACQUES DeMORTIER, M.D. Boston
 Laboratory for Surgical Research, Harvard Medical School

THE purpose of this experimentation was to determine the degree of infectibility of simple incised and sutured wounds subsequently swabbed with a culture of pathogenic organisms after various intervals of time.

Howes, Sox, and Harvey studied the rate of healing of clean incised sutured wounds in dogs by mensuration of the tensile strength of these wounds at definite intervals. They concluded that there exists a quiescent phase or lag period of from 4 to 5 days characterized by fibrin formation in the blood or plasma exuded between the surfaces of the fresh wound. During this interval the approximation of the incised tissue is dependent upon the mechanical coaptation of its sutures. From the sixth day on, however—

the period of fibroplasia, manifest by multiplying fibroblasts and sprouting blood vessels—the wound rapidly develops intrinsic holding power until from the tenth to the fourteenth day its tensile strength reaches a maximum comparable to that of unincised tissue.

Carrel (3) studied the mechanisms of the repair of surgically aseptic cutaneous open wounds in dogs by measurement of the variations in their dimensions. He showed that there is a quiescent period lasting from 1 to 5 days during which the dimensions of the wound do not vary. This is followed abruptly by a period of granulous retraction. The rate of reparation of the granulous period is directly proportional to the size of the wound. The end of this period coincides with the beginning of the period of epidermization which is inversely proportional to the dimensions of the wound. This period is succeeded by the period of cicatrization, of considerable length, during which progressive enlargement of the scar occurs. In a later report, Carrel and LeComte Du Notty (4) state that the latent period of cicatrization in dogs varies generally from 5 to 7 days. It stops abruptly and contraction starts with

maximum velocity. Carrel and Hartmann (5) found in subsequent experiments that when a surgically aseptic open wound becomes infected, arrest or regression of the repair occurs, yet the senior author states that the application of turpentine chick embryo and staphylococci decreases markedly the length of the latent period often to less than 2 days. This work is of considerable interest in relationship to our findings.

Billroth, one of the first to make a study of wound infections, demonstrated that granulating surfaces offer considerable resistance to infection. Virulent organisms, implanted on granulating tissues of dogs, cause no infection, but these same bacteria inoculated into fresh wounds result in extensive infection in some instances leading to the death of the animal. He believed that this resistance of granulation tissue is due to lack of lymphatics. Noetzel and Afanasieff working on absorption of poisons from granulating tissues, both independently came to the conclusion that granulation tissue affords considerable protection against the invasion of bacteria. Halley, Chesney and Dresel, demonstrated that granulations constitute a relatively unfavorable environment for the survival and growth of *Streptococcus erysipelatis* and *Staphylococcus aureus*.

It is a clinical truism on the other hand that fresh wounds are readily infected. In 1897 Schimmelbusch and Ricker showed that there is rapid absorption of both pathogenic and saprophytic bacteria from fresh bleeding wounds. W. H. Welch states: The period during which the rapid absorption of bacteria from a fresh wound takes place is of short duration. As soon as a coagulum has formed on the surface of the wound, the open mouths of lymphatics and blood vessels are plugged, the conditions have changed and fine particles like bacteria are no longer quickly transported into the intact lymphatics and blood circulation. The surface of a healthy granulating wound offers great resistance to the invasion

of bacteria almost as much as an intact exposed surface of the body. Slight injuries, such as probing removal of dressings and other manipulations may convert a granulating surface into a fresh wound with accompanying dangers of infection."

However, from an experimental point of view that period in which an operative incision changes from an excellent locus of infection to one offering protection comparable to that of intact epidermis is not known. That period in healing, in which a wound may be manipulated without danger of resulting infection through surface implantation of organisms whether by wilful or unintentional abandonment of the principles of asepsis has not been demonstrated.

PROCEDURE

From the Surgical Wards of the Peter Bent Brigham Hospital a 24 hour broth culture of *Staphylococcus aureus* hemolyticus was obtained from an abscess of the buttock, 0.5 cubic centimeter of this culture was injected subcutaneously into each of four guinea pigs, and in three days all developed typical abscesses. Smears of the pus demonstrated the organisms in pure strain. This strain was kept on plain agar and its virulence maintained and checked by weekly inoculations into guinea pigs. Six hours prior to its experimental use it was transferred to dextrose infusion broth, 0.5 cubic centimeter of this 6-hour broth culture being used in each of the experiments.

The operative technique in all experiments was the same. The abdomen of each pig was widely shaved and cleansed with green soap and water. The operative field was carefully prepared with 70 per cent alcohol and bichloride of mercury (1:4000). The abdomen was draped in the usual manner. Under ether anesthesia an incision 5 centimeters in length was made through the skin subcutaneous tissue and abdominal musculature. Hemostasis was assured. The musculature was then carefully approximated with interrupted fine black silk sutures and the skin closed in like manner care being taken to leave no dead spaces or gaping edges. A sterile dressing was applied and kept intact

with adhesive, simulating Montgomery straps. These were found very satisfactory and anchored the dressing down tightly. To guard further against contamination of the wound the animal's legs were fastened with rubber bands which necessitated the maintenance of a dorsal position.

Thirty incisions were made in each series of experiments, except the first in which forty two were made. In the first series no organisms were implanted, in the second, immediately at the close of operation 0.5 cubic centimeter of a broth culture of *Staphylococcus aureus* hemolyticus obtained as described above was gently swabbed along the operative site, and a sterile dressing applied. In the third, 2 hours were allowed to elapse before the sutured wound was similarly treated, in the fourth series 6 hours, in the fifth, 12 in the sixth 24, and then 24 hours later in each subsequent series. Control experiments were performed both independently and in conjunction with each series as to the virulence of the organisms, the resistance of the intact skin to resist these organisms and on the ability of the un inoculated wound to heal by first intention.

RESULTS

1. Operative incisions in guinea pigs, made and followed with aseptic technique, heal by first intention. In 42 operative procedures 41 wounds healed without infection. One developed a small stitch abscess on the fifth day. Stitches were removed routinely on the sixth day, and on the eleventh day the scars were scarcely discernible.

2. *Staphylococcus aureus* hemolyticus implanted upon the intact skin does not cause infection. The organisms were smeared on the shaved abdominal wall of forty guinea pigs. No infection occurred.

3. In the first series of 30 animals *Staphylococcus aureus* hemolyticus was implanted along the line of closure at the completion of the operative procedure. Within 4 days gross infection was present in all cases. Four guinea pigs died of overwhelming infection within 3 days, 3 had extensive spreading infections of the anterior abdominal wall, 20 developed gross abscesses in the subcutaneous

tissue and muscle layers and 3 an accumulation of suppurative fluid beneath the skin. Microscopic sections confirmed the gross findings. Gram stains revealed staphylococci in great numbers. The three control incisions healed without infection.

4 In the second series *Staphylococcus aureus hemolyticus* were implanted upon the sutured wound 2 hours after operation. Gross infection was apparent in all incisions within 4 days. Five guinea pigs died of overwhelming infection within 3 days. Two developed an extensive spreading infection of the anterior abdominal wall. Twenty-two had gross abscesses and one an accumulation of suppurative fluid beneath the skin. The controls were uninfected. Their findings were substantiated by microscopic examinations. Large numbers of staphylococci were found in all inoculated incisions.

5 In the third series staphylococci were implanted upon the sutured wound 6 hours after operation. Infection was present in all incisions within 4 days. One pig died of overwhelming infection within 3 days. There were no extensive infections of the abdominal wall. Twenty-eight incisions developed gross abscesses. One incision showed no evidence of infection grossly but microscopic examination revealed its presence. The control incisions healed by first intention. The organisms were found in large numbers in all the infected wounds. In general, the infections were less extensive in this series than in the two preceding ones.

6 In the fourth series staphylococci were implanted upon the sutured wound 12 hours after operation. Infection was present in 83 per cent of the incisions within 4 days after implantation of the organisms. There were no deaths and no extensive infections in contrast to the previous series. Twenty-one incisions contained gross abscesses. Microscopic evidence of infection was found in four incisions though not manifest grossly. Five (17 per cent) showed no gross or microscopic evidence of infection. The control incisions healed *per primam*. The organisms were demonstrated in all the infected wounds. There was a marked decrease in the severity of infections in this series.

7 In the fifth series, staphylococci were implanted upon the sutured wound 24 hours after operation. Infection was present in 66 per cent of the incisions within 4 days, after the implantation of organisms. There were no deaths and no extensive infections. Fifteen wounds had gross abscesses, only one of which was at all severe. Staphylococci were present in these lesions. Five showed unmistakable evidences of infection microscopically, which was not apparent grossly. In 4 of those incisions demonstrated to have infection only by microscopic means no organisms were found. Ten incisions (33 per cent) were healing *per primam intentionem*. The controls were negative.

8 In the sixth series staphylococci were implanted upon the sutured wound 2 days after operation. Infection was present in 56 per cent of the incisions within 4 days after the implantation of organisms. There were no deaths and no extensive infections. Thirteen incisions were found to have gross abscesses, two of which were severe. Four incisions showed no gross evidence of infection but microscopic sections revealed its presence. Thirteen incisions (44 per cent) were healing by first intention. Staphylococci were present in all the gross lesions, and in 3 of the 4 microscopic lesions. The controls were negative.

9 In the seventh series staphylococci were implanted upon the sutured wound 3 days after operation. Infection was present in 36 per cent of the incisions within 4 days after the implantation of organisms. Six incisions contained gross abscesses, in all of which staphylococci were found. None of these abscesses were over 0.5 centimeter in diameter. Five wounds showed evidence of infection on cut section although not visible grossly. In 2 of these staphylococci were identified. Nine incisions (64 per cent) showed no evidence of infection. The controls were negative.

10 In the eighth series staphylococci were implanted upon the sutured wound 4 days after operation. Infection was present in 10 per cent of the incisions within 4 days after the implantation of organisms. One incision was found to have a gross abscess 0.1 centimeter in diameter in which the staphylococcus was identified. Two showed unmistakable

Fig. 1. Curve showing relationship of infection to time of implantation of organisms in sutured wounds.

evidence of infection microscopically but not grossly. No organisms were shown in these two sections. Twenty seven (90 per cent) healed by first intention. The controls were negative.

11 In the ninth series staphylococci were implanted upon the sutured wound 3 days after operation. Gross and microscopic examination revealed no infection.

12 In the tenth series staphylococci were implanted upon the wound 6 days after operation, immediately following the removal of all skin silks. No infections could be demonstrated either grossly or microscopically. In 7 instances the wound was partially reopened while pulling out the stitches and the organisms were swabbed into the defect without resulting infection.

13 In the eleventh series, staphylococci were implanted upon the wound 7 days after operation and 24 hours following the removal of the skin silks. No infections could be demonstrated either grossly or microscopically. On the eleventh day after operation, when the wounds were examined it was only with difficulty that the operative incision could be identified.

DEDUCTIONS

These results demonstrate that after an incision of tissue there follows a well defined

period about 6 hours in length in which that tissue's resistance to invasion by bacteria is at a minimum. In this period bacteria not only flourish and cause suppuration in the local lesion but invade without apparent restraint the adjoining tissues, setting up extensive, rapidly spreading infections which in a number of instances result in the death of the animal. After this period, however, the factors concerned in the repair and protection of tissue become increasingly apparent. When organisms are implanted upon a sutured wound 12 hours after operation, although the great majority of incisions become infected (83 per cent) the infections are localized. No systemic infections develop, which overwhelm the animal, and no extensive spreading suppuration occurs. From this time on, the percentage and severity of infections steadily decreases (see Table I) until between the fourth and fifth post-operative days it is no longer possible to cause infection by implantation of virulent organisms on the surface of the wound (see graph).

This period of from 4 to 5 days coincides with the 'lag period' of healing wounds, described by Harvey (7) and by Carrel (3) and which Harvey points out is common to all growth phenomena. This period is charac-

TABLE I.—DURATION OF INFECTION

Degree of infection	Time of implantation of <i>Staphylococcus aureus</i> following operation										
		1 hr	6 hr	1 hr	24 hr	days	2 days	4 days	5 days	6 days	7 days
Severe		3	2	7							
Abscess 1 cm in diameter	5		2								
Abscess 3 cm in diameter		3	5	5	4	4	3				
Abscess 2-3 cm in diameter	3			5	5	3					
Abscess 1-2 cm in diameter						3

tenized by fibrin formation in the blood or plasma exuded between the surfaces of the fresh wound. This fibrin formation apparently has but little resistance against the invasion or multiplication of bacteria and it is only when it has been replaced by fibroblasts that protection against bacterial invasion becomes complete. It would seem therefore, that resistance to infection is not complete until the lag period of a healing wound (4 to 5 days) has been succeeded by what Harvey speaks of as the period of fibroplasia—manifest by multiplying fibroblasts and sprouting blood vessels.

It is of clinical importance that for the first 5 days following an operative incision extreme care be taken in the manipulation of a wound as during this period infection is possible from implantation of virulent organisms on its surface.

On first thought it might seem surprising that when virulent organisms are implanted along a wound on the sixth day immediately following the removal of stitches no infection results. However upon consideration that these stitches have become walled off by granulation tissue which is highly resistant to the invasion of bacteria, it is readily understood. Even in those instances in which due to a sudden movement of the animal while removing a stitch, a small segment of the wound was reopened no infection developed although the organisms were swabbed into this defect. This is likewise explainable upon the same factor of resistance of granulation tissue to the invasion of bacteria.

SUMMARY

1. The resistance of a healing wound to infection is minimal during the first 6 hours.
2. After the first 6 hours infections decrease in number and severity until fifth day.
3. On the fifth day after operation, the resistance of a wound to infection has reached a level comparable to that of intact tissue.
4. Removal of stitches on the sixth day after operation does not lower the resistance of the wound to infection.
5. The period of infection corresponds to the lag period of healing wounds.

THE SURGICAL REMOVAL AND HISTOLOGICAL STUDIES OF SYMPATHETIC GANGLIA IN RAYNAUD'S DISEASE, THROMBO-ANGIITIS OBLITERANS, CHRONIC INFECTIOUS ARTHRITIS, AND SCLERODERMA

WINCHELL McA. CRAIG M.D., F.A.C.S. ROCHESTER, MINNESOTA
Division of Surgery The Mayo Clinic

JAMES W. KERNOHAN M.D. ROCHESTER, MINNESOTA
Section on Pathologic Anatomy The Mayo Clinic

THE surgical removal of sympathetic ganglia has been followed by relief of symptoms in selected cases of Raynaud's disease (2) thromboangitis obliterans (3) chronic infectious arthritis (19) and the acral type of scleroderma (4) but studies of the ganglia removed have been inadequate to determine the presence of any constant histological changes.

Operations consisting of the removal of ganglia have stimulated interest in the clinical physiological and pathological aspects of the sympathetic nervous system. This study is based on 308 cases in which the cervicothoracic sympathetic ganglia were removed to obtain sympathetic denervation of the upper extremities and the second, third and fourth lumbar sympathetic ganglia were removed to obtain sympathetic denervation of the lower extremities. In all cases removal of the cervicothoracic ganglia was carried out according to the technique described by Adson (1) consisting of posteromedian incision over the lower cervical and upper thoracic vertebrae followed by the bilateral removal of the transverse process and a portion of either the first or second rib permitting entrance into the posterior mediastinum and access to the cervicothoracic sympathetic trunk. The lumbar sympathetic trunk was removed through a median abdominal and bilateral transperitoneal incision, the second, third, and fourth sympathetic ganglia on both sides at the same operation (2) being removed.

In a certain number of operations for the removal of sympathetic ganglia, indications of inflammatory reaction in both the posterior mediastinum and in the postperitoneal tissues were found. In the abdomen enlarged lymph nodes frequently interfered with the exposure

of the sympathetic chain to such an extent that it was necessary to dissect and remove them before the operation could be completed. Although enlarged lymph nodes were not encountered in the posterior mediastinum the difficulty of dissecting the sympathetic trunk due to adhesions suggested the presence of mild mediastinitis. These observations at operation raised the question of local inflammatory reaction playing some part in the dysfunction of the sympathetic system by involving the ganglion tissues and cells. Consequently we have been making a study of the ganglia removed at operation and not only have examined them histologically but have cultured them on different mediums to investigate possible bacterial invasion. The ganglia which have been removed have been kept sterile emulsified and cultured in glucose brain broth and brain agar. In only a few instances have there been any positive cultures and these Rosenow reported as consisting of pleomorphic streptococci.

The local inflammatory reaction about the sympathetic ganglia in the operative cases aroused our interest to such a point that observations were made in 40 non-operative cases at postmortem in which derangement of function of the sympathetic nervous system had not been apparent. It was surprising to find that in a large percentage of these cases the lymph nodes lying postperitoneally along the vertebral column and superimposed on the lumbar sympathetic chain were enlarged and simulated the picture seen at operation but this could not be established as an inflammatory process.

In order to correlate the clinical, surgical and pathological aspect of these cases, we have tabulated our histological observations to correspond to the clinical diagnoses and

although all the ganglia have been investigated we are presenting four clinical histories from the entire group of cases as a background of our pathological considerations. These cases have been chosen not only because they represent the diagnostic groups, but also because they responded exceptionally well to the therapeutic application of sympathetic ganglionectomy. Therefore any pathological changes occurring in the ganglia should have been evident in these cases.

In the cases of Raynaud's disease, 50 were submitted to operation in some of them bilateral lumbar ganglionectomy in some bilateral cervicothoracic ganglionectomy and in others both operations were done.

RAYNAUD'S DISEASE

This disease occurs in adult life, predominating in women and is characterized by the presence of symmetric changes in the color of the hands and feet or of the fingers and toes. It may involve the upper or lower extremities, and occasionally the nose and the lobes of the ears. The blanching of the skin is brought about by vasoconstriction of the vessels, due to exposure to cold or emotional influences. This blanching is followed by cyanosis, which continues until the vasoconstriction subsides. In the earlier stages of the disease, this subsidence is accompanied by discomfort, then by aching and finally by severe pain. As the disease progresses the changes in color become more prominent and the skin remains more or less cyanosed unless the condition is relieved by the application of heat externally. Should the vasoconstriction become prolonged and the circulation markedly decreased gangrene may occur. Gangrene in Raynaud's disease differs from the gangrene which occurs when the vessels are occluded in that it produces dry ulcers at the tips of the fingers or toes with distorted growth of the nails, instead of complete gangrene of one of the digits. If the process is allowed to continue the gangrene will ascend and will become extremely painful. Usually the patient complains of subjective numbness, which interferes with the function of the extremity and adds to the general discomfort and incapacitation. The disease does not always progress to

the severe forms hence the milder forms may be controlled by changing occupation or climate. When the symptoms persist, and ulceration and gangrene develop operation should be performed. In almost all the cases in which operation has been performed, the relief of pain is almost instantaneous, the cyanosis disappears and the skin becomes warm pink and dry the ulcers heal the nails take on normal growth, and the patient is restored to normal health.

Illustrative case. A woman, aged 25 years, gave a history of blanching of the right index finger 3 years previous to registering at The Mayo Clinic. This came on during the winter months, but disappeared in summer. The next winter, however the condition became gradually worse, both hands becoming cyanotic to the wrists, associated with numbness and dull aching pain. This did not clear up with the advent of warm weather and the following winter small dry ulcers developed in different finger tips, and the feet also began to manifest the symptoms of color changes and pain when exposed to cold.

General examination was essentially negative except for marked vasomotor changes in the extremities. A diagnosis of Raynaud's disease was made, and because the hands were more involved than the feet cervicothoracic sympathetic ganglionectomy was performed. The stellate and second thoracic sympathetic ganglia were removed from both the right and left sides (Fig. 1). The patient's convalescence was uneventful and she was completely relieved of cold, blue, numb hands 15 days after operation the ulcers on the tips of the fingers had completely healed.

An interval of 6 weeks was allowed to elapse before operative interference to relieve the lower extremities was thought advisable. The patient's complaint concerning her feet was similar to that concerning her hands in that there were marked grades of cyanosis on exposure to cold, mild pain, numbness, and tingling followed by periods of recovery during which there was burning, redness, and sweating. The symptoms were completely relieved after bilateral lumbar sympathetic ganglionectomy at which time the second, third, and fourth lumbar sympathetic ganglia were removed on both sides (Fig. 2).

In these as in all the other ganglia removed various points were noted. The blood vessels showed a mild degree of thickening of the wall with subsequent narrowing of the lumen so that the ratio of lumen to wall which is normally 2 to 1 in small arteries was now only 1.7 to 1. In addition in a few arterioles there was an increase in prominence of the lining endo-

thelial cells, but this was by no means universal and was present only in a mild degree. There was no evidence of acute or chronic inflammation, there were no fibroblasts or increase in the connective tissue as shown by the van Gieson stain, and polymorphonuclear leucocytes were not present. Although there was no inflammation lymphocyte like cells were present and these were in two small groups and not scattered diffusely throughout the ganglia. At one end of the ganglia there was slight edema of the connective tissue. This varied greatly in the various ganglia removed for this condition and was never pronounced. Besides the stains used as a routine, thionin stain, Orlandi silver impregnation method, Horta's silver carbonate method and Cajal's gold chloride and sublimate method were employed in the study of the ganglion cells. In the case under consideration there was little change in any of the cells other than that seen normally. There was slight chromatolysis in less than a third of the cells and slight vacuolization in the periphery of some of the others. This was not advanced and was present in about half of the cells. In the same cells some of the endocapsular cells were prominent, and the vacuoles in the periphery of the ganglion cells appeared to be caused by swelling of the endocapsular cells. Some of the capsular cells thus appeared as deep-staining nuclei with clear spaces around them causing excavations of the cytoplasm of the underlying ganglion cells. Only occasionally was there any demonstrable increase in the ectocapsular cells. The various special stains were unsatisfactory in demonstrating the bodies of the endocapsular cells. In a seventh of the ganglion cells pigment granules were not present, whereas in about five sevenths a slight amount was present (graded 1) and in the remaining seventh there was considerable pigment (graded 2). This is a normal phenomenon and is seen constantly in increasing amounts in normal ganglia with advancing age. In ganglia removed from patients with Raynaud's disease in the group in which there was no pigment, the average age of the patients was 24.3 years, in the group in which pigment was graded 1, the average age was

33.7 years, and in the group in which it was graded 2 the average age was 40 years, thus conforming to the tendency for increased pigment deposition in many nerve cells, especially sympathetic ganglia with advancing age. There is, in any control series of ganglia, a marked variation in pigment precipitation, but it is almost always more abundant in the ganglion cells of older persons than in those of younger persons.

THROMBO-ANGITIS OBLITERANS

There were 97 patients with thrombo-angitis obliterans on whom the cervico-thoracic or lumbar ganglionectomy or both types of operation were performed and the ganglia removed were studied histologically.

Thrombo-angitis obliterans occurs in adult life, has a predilection for men and affects persons of all races in spite of the fact that it formerly was supposed to occur more commonly among Jews. The underlying causes have not all been determined. The disease seems to progress after infection of the inner walls of the arteries and formation of a clot which occludes the vessels, thus decreasing the blood supply to the extremity. The infection and the formation of the clot vary in degree and distribution. The condition may affect the distal part of one principal artery, or it may include all the principal arteries of all extremities at different periods. The usual course of this disease is rather slow; the main vessels of the feet and legs become involved early and those of the upper extremity later. When it is economically possible relief can be obtained by discontinuing work, remaining at rest in bed, applying heat to the extremities and being treated with vaccines administered intravenously. In time organization of the intravascular clot takes place and circulation is restored. However many patients are compelled to work, subjecting their hands and feet to trauma, and ulcers may develop sooner or later and refuse to heal. These ulcers become infected, the infection spreads to the adjacent tissues, and more thrombosis and gangrene appear, necessitating amputation of the extremity (9). By means of operations on the sympathetic system, it is possible to relieve the vasomotor spasm of the col-

lateral vessels, which improves circulation tends to prevent ulceration infection and gangrene and hastens healing of existing ulcers and abrasions. In suitable cases selected by means of the various tests of altered vasoconstriction [Brown's fever test (7) White's (22) diagnostic nerve block and White (22) Morton and Scott's (16) spinal anesthesia test] the temperature of the skin is increased from 2 to 10 degrees, depending on the amount of vasoconstriction present before the operation, the ulcers begin to heal and the patient is restored to his former status as a wage earner. Moreover the operation may prevent further gangrene and extension of the process to the opposite extremity which usually is involved to a slighter degree than the extremity which causes the symptoms. Operation is not advised for milder cases in which the patients are not inconvenienced greatly, are free from ulcers, and are able to carry on regular work under symptomatic treatment. The normal expectancy for amputation of one or more limbs in cases of thrombo-angitis obliterans even under ideal conditions is more than 25 per cent, but there has been a definite reduction of this percentage in cases in which sympathetic ganglionectomy has been performed. Less than 5 per cent of the patients who have left the clinic following operations on the sympathetic ganglia have been obliged to submit to subsequent amputation (6). This comparison emphasizes the value of operations on the sympathetic system in protecting patients with thrombo-angitis obliterans from losing one or more extremity by amputation.

Illustrative case. A man aged 35 years, came to the clinic complaining of pain in the feet and legs associated with ulcers and cyanosis of the toes. His history dated back almost 12 years, when after trauma to the right instep he experienced intermittent pain in walking. Six years following this, cyanosis, rest pain, and ulceration in the right little toe developed, which proved very indolent to treatment. Five years after the trouble with the little toe began, a similar condition developed in both great toes and the ulcers remained open for several months. Following this, cyanosis occurred in both feet, and intermittent pain developed. Two months before registration at the clinic, the four lateral toes on the left foot became blue and cold, and ulceration occurred between third and fourth and fourth and fifth toes.

On examination the lower extremities were cold and blue. The femoral and popliteal pulses were present on both sides, the posterior tibial artery on the right was partially occluded and completely occluded on the left, both dorsalis pedis arteries were occluded. The right foot was cold and dark, but did not contain ulcers, the left foot was cyanotic, especially over the lateral portion, and indolent ulcers were present between the third and fourth and the fourth and fifth toes.

A diagnosis was made of thrombo-angitis obliterans with vascular insufficiency. Intravenous typhoid vaccine was given which was followed by increase of surface temperature sufficient for a satisfactory vasomotor index. Bilateral lumbar sympathetic ganglionectomy was carried out, and the second, third, and fourth lumbar sympathetic ganglia were removed (Fig. 1). There was evidence of an inflammatory reaction about both sympathetic chains. The patient recovered uneventfully and when seen almost a year after operation, he was working and was well satisfied with the result obtained in his case.

Histological study of the ganglia showed that there was more proliferation of the lining endothelial cells of the arterioles and small arteries than in the cases of Raynaud's disease which we have studied, but this proliferation was by no means universal. There was also slight thickening of the walls of the larger vessels present in the ganglia, so that the normal ratio of lumen to wall (2 to 1) was reduced to 1.8 to 1 and is thus less than that seen in the vessels examined in cases of Raynaud's disease. There was no evidence of acute or chronic inflammation. Fibroblasts were not present and excessive connective tissue was absent as demonstrated by special staining methods. Several small collections of lymphocyte-like cells were present, but none were scattered diffusely throughout the ganglia. The groups were not associated with blood vessels. There was mild edema of the connective tissue, but this was not universal in the ganglia. The edema was more marked in the ganglia removed from patients suffering from thrombo-angitis obliterans than from any other ganglia studied. Special staining methods were employed in studying the ganglion cells themselves, but the changes that were present were very slight. There was a mild degree of chromatolysis in about a seventh of all the cells whereas a fourth were normal. In more than half of the cells small vacuoles were present at the periphery and these corresponded

in situation to the endocapsular cells. The vacuoles appeared to have been caused by swelling of the endocapsular cells, the nuclei of which were prominent and cytoplasm could be demonstrated only with difficulty with the special stains that is, Cajal's gold chloride and sublimate method and Hortega's silver carbonate method for microglia and oligodendroglia. The deep-staining nuclei were surrounded by a clear space such as is seen in acutely swollen oligodendroglial cells described by Penheld and Cone. Mucus stains revealed only slight traces of some of these vacuoles. There were several cells which had been replaced by large vacuoles and remnants of the ganglion cells were compressed at one part of the periphery against the cell capsule. This process of vacuolar degeneration or destruction seemed to be different from changes brought about by swelling of the endocapsular cells. The swollen endocapsular cells corresponded closely to the vacuolization present in the periphery of cytoplasm of the ganglion cells. Pigment was present in the cytoplasm of more than 90 per cent of the ganglion cells but was slight in amount in 75 per cent of the cells. There was considerable pigment in 20 per cent of the cells and there were few cells in which there was pigment graded 3. The average age of the patients with thrombo-angitis obliterans was 35.7 years. The average age of patients with out pigment in the ganglion cells was 29.6 years, of those with pigment graded 1 the average age was 36.8 years and of those graded 2 the average age was 46 years, the one patient with pigment graded 3 was aged 53 years. This again conforms with the tendency for pigment to increase with advancing age in nerve cells and especially in the sympathetic ganglion cells.

ARTHRITIS

Ganglia from 46 patients with arthritis were studied histologically. In some cases both the upper or lower extremities were denervated, and in others all four extremities.

Among the various types of patients suffering from chronic infectious arthritis are young adults who have painful swollen tender joints, associated with limited motion, atro-

phy of the muscles, and loss of function. Patients complain also of cold extremities, mild changes in color of fingers and toes and excessive perspiration. There is a tendency for the condition to progress slowly, it is not altered by removal of foci, immobilization, massage or exercise, and is symptomatically relieved only by the application of various types of heat. In certain selected cases of this group operations on the sympathetic ganglia are followed by relief of symptoms and by the improvement in circulation which follows the vasodilatation (+). The skin becomes warm and dry and pain is generally relieved; the tenderness tends to disappear and the swelling subsides. In selecting suitable cases for the operation the rise in surface temperature of the extremity following intravenous administration of typhoid vaccine is used as an index, and if there is no appreciable rise in surface temperature or relief of symptoms following protein injections the operation is not indicated.

The following case is reported because it presents the salient features of a slowly progressive arthritis not yielding to the usual therapeutic measures. The associated vasomotor changes as evidenced by the cold clammy extremities which were temporarily relieved by the intravenous administration of typhoid vaccine formed the basis for sympathectomy. The history of psoriasis and the presence of mild lesions at the time of examination raised the question of a differential diagnosis of chronic infectious arthritis and arthropathia psoriatica (13). The clinical features, however, were those of the former and the excellent response to operation rendered this case most suitable for histological study.

Illustrative case. A man, aged 40 years, came to the clinic complaining of pain, stiffness, and deformity in the fingers and toes. Four years before admission he began to have swelling, redness, and pain in the right index finger. The remaining digits of the right hand became similarly involved and gradually the left hand became affected with the same process. The condition progressed and after 2 years had elapsed the toes on both feet began to swell and to become painful and stiff. The arches ached with activity but were relieved by rest. This condition progressed to the point where the patient was unable to walk or use his hands without pain and discomfort.

Examination disclosed areas of paresthesia on the upper midsacral regions and outer surface of the right leg which had been present intermittently for the previous 6 years. There was moderate swelling of the left wrist with tenderness and to per cent limitation of dorsal flexion. Both hands were cold and slightly clammy with swelling and motion of phalangeal joints was limited. There were trophic changes in the fingernails. Both feet were cold and clammy. There was marked swelling and tenderness at the base of the toes on both feet and tenderness on pressure over both arches. Both hands and feet were cyanotic. Roentgenograms revealed healed tuberculous lesions in the upper part of the right lung. One dead tooth was found, and removed. Mild prostatitis was treated. Because of the evident associated vasomotor spasm of the peripheral arteries, typhoid vaccine was given intravenously which was followed by marked relief of pain and the skin over the extremities became warm and pink. When the surface temperature was compared with that taken before the injection had been given, a marked rise had taken place, thus establishing a satisfactory vasomotor index.

Bilateral lumbar sympathetic ganglionectomy (Fig. 1) was performed. The second, third, and fourth lumbar sympathetic ganglia were resected on both sides. There was a marked inflammatory reaction about the sympathetic chain and the overlying lymph nodes were enlarged and inflamed. The lymph nodes were removed and microscopic section revealed fatty fibrosis with inflammatory nodules. Following an uneventful convalescence, the patient was relieved of almost all the pain in both feet; they became warm and cyanosis disappeared.

The question of cervicothoracic sympathectomy was considered, but the patient wished to wait for time to evaluate the improvement in the lower extremities. Six months later examination revealed increased severity of the condition of the hands. The patient was walking without pain, his feet were warm and dry, and he requested that a second operation be considered. Bilateral cervicothoracic sympathetic ganglionectomy (Fig. 2) was done, removing the stellate and second thoracic ganglia after resecting the transverse process and part of the first rib. Marked alleviation of pain in both hands followed. After an uninterrupted convalescence the patient returned home, continuing to improve until he could use his hands without pain and with very little residual stiffness (Fig. 3).

The changes observed histologically in these ganglia were similar to those described in the ganglia removed from patients suffering from Raynaud's disease and thrombo-angitis obliterans. Most of the blood vessels were normal but in a few there was mild proliferation of the lining endothelium of the intima and in others there was slight thickening of the walls of the larger arteries in the ganglia.

The ratio of lumen to wall in this group was 1.8 to 1 instead of the normal 2 to 1. There was no evidence of acute or chronic inflammation; polymorphonuclear leucocytes were not present; fibroblasts were absent, and there was no increase in adult connective tissue. Although there was no inflammation there were small collections of lymphocyte-like cells but these were collected in groups and not scattered diffusely throughout the ganglia. In the ganglia removed from patients suffering from arthritis slightly less than 50 per cent contained similar small collections of these lymphocyte-like cells. There was a slight amount of edema in the ganglia, but it was localized, and varied greatly in the other ganglia removed for this condition. Special stains were utilized in studying the ganglion cells, and approximately two-fifths of the cells were normal, one-fifth of them manifested a mild degree of chromatolysis and a few cells were pyknotic. In approximately two-fifths of the cells there was vacuolization at the periphery and this corresponded to what seemed to be swollen endocapsular cells. This vacuolization was mild in most of the cells in which it was present but in a few cells it was quite prominent. The swollen endocapsular cells corresponded in situation to the vacuoles in the periphery of the ganglion cells. In an eighth of the ganglion cells pigment was not present in the cytoplasm whereas in three-fourths there was a slight amount of pigment (graded 1) and in the remaining eighth it was more pronounced (graded 2). The average age of the patients suffering from arthritis was 30.7 years. The average age of those whose ganglia contained pigment less than grade 1 was 19 years, of those with pigment graded 1 31.9 years, of those with pigment graded 2 35 years and of the one patient whose ganglion cells contained pigment graded 3 the age was 53 years. These observations again support the opinion that pigment in sympathetic ganglion cells increases with age and is not necessarily a manifestation of the disease process.

SCLERODERMA

Scleroderma is sometimes alleviated by sympathetic ganglionectomy. The condition

of the skin is characterized principally by brownish discoloration associated with thickening or atrophy, usually involving the fingers and toes. The distribution may be circumscribed, spotty or diffuse, and limited to the feet and legs or it may involve the hands, arms, face and neck, and the skin over the upper part of the thorax. The muscles and bones may be included in the atrophic and degenerative process. The disease is usually slowly progressive and it occurs at any age or among persons of either sex but more frequently among young women. All cases of scleroderma do not result from disturbances in the sympathetic nervous system, but the lesions of the feet, legs, hands, arms and face frequently are preceded by a phase of increased vasoconstriction characterized by cold, sweaty bluish hands and feet similar to those of Raynaud's disease(2). This type of scleroderma has been observed also in cases of thrombo-angitis obliterans and chronic infectious arthritis. The early cases of scleroderma associated with vasomotor changes, sometimes respond satisfactorily to operation on the sympathetic nervous system, but in advanced cases there is no marked improvement, because of the pathological changes that have taken place in vessels, skin and subcutaneous tissues (8-17). The results in the early cases are those of immediate improvement in circulation and loosening and thinning of the skin over the extremities, face, and neck. The skin and muscles of the face lose their drawn expression, the mouth can be opened more widely and the tongue can be protruded. The operation will not help in advanced cases in which thickening of the skin and hardness of the muscles have become extreme and therefore if operation on the sympathetic system is to be employed in the treatment of scleroderma of vascular origin it should be employed as soon as the disease is recognized in order to prevent its progress. If the condition is permitted to continue it usually results in pain, deformity, and total invalidism.

In 16 cases of scleroderma of the vasomotor type operation has been done and sympathetic ganglia have been removed. The following case was selected from the group be-

cause of the history and definite improvement following operation. We have assumed that histological changes, if present, should be discernible in the removed ganglia of successful cases.

Illustrative case. A woman aged 48 years, came to the clinic complaining of stiffness of the hands associated with thickening of the skin over the thorax and face. Her history revealed attacks of increasing severity in which on exposure to cold all of the fingers and toes first became white and cold then blue and finally red and warm. After many years these symptoms became more pronounced, and the skin of the hands, arms, thorax and face began to lose its flexibility, resulting in retarded motion. Exposure to cold intensified all symptoms.

General examination was essentially negative except for the changes incident to the scleroderma. There was evident thickening of the skin of the face the wrinkles being ironed out, and definite limitation of motion on opening the mouth and protruding the tongue. The skin over the thorax had a definite sheen and could not be rolled under the fingers. The hands appeared waxy, the fingers were stiff and permitted about 25 per cent flexion. The joints of the fingers were enlarged and tender to pressure and the hands were cold and moist.

Because of the evident association of vasomotor spasm and the failure of other types of treatment to control the progress of the disease, sympathetic ganglionectomy was carried out and the stellate and second thoracic ganglia were removed from each side (Fig. 1). As early as the seventh day following operation, a decided change in the facial expression was noted, the normal pink hue had replaced the waxy appearance and the skin was decidedly softer. There was also a slight increase in skin temperature. The stiffness of the hands began to improve until by the fifteenth day after operation the skin of the fingers up to the first joints was normal in appearance. All the fingers were warm, but the mobility was not increased. The mouth could be opened wider and the tongue protruded farther.

One year and 10 months after operation the patient returned and her general condition was found to be excellent. There was definite improvement in the scleroderma of the hands, thorax, and face. The hands were warm and, although a little stiff, had shown great improvement.

Slight changes were noted in the ganglia similar to those in the ganglia removed for the lesions mentioned already. Most of the arterioles and small arteries in the ganglia were normal, and in a few there was slight proliferation of the lining endothelial cells of the intima. There was no thickening of the walls of the vessels, and the normal ratio of wall to lumen was constant throughout. There was

no inflammation acute or chronic, and there was no increase of the connective tissue al though there was a slight amount of edema, but this was not universal throughout the ganglia. It was present in less than 50 per cent of the cases. Although there was no inflammation there were small collections of lymphocyte like cells in the ganglia in this case but in the ganglia from the entire group it was present in only 30 per cent. In the ganglion cells themselves there was slight chromatolysis in a few approximately 25 per cent and in the entire group of ganglia removed from patients suffering from scleroderma chromatolysis was present to this degree in only 30 per cent. As in ganglia studied from all conditions there was vacuolization of the periphery of the cytoplasm of the cells and this corresponded to the swollen endocapsular cells. This proliferation corresponded in degree and site to the vacuolization of the cytoplasm of the ganglion cells. Pigmentation was visible in most of the cells, but was usually slight. It was present in the same mild degree in 75 per cent of the ganglia removed for this condition. The average age of the patients in the entire group was 35 years. In the cases in which there was no pigment the average age was 27.5 years, in the group in which pigment was graded 1 the average age was 37 years. Pigment was not graded more than 1 in any case. The finding of pigment in the ganglion cells supports the observations made in ganglia removed for the other conditions that there is a deposition of pigment with advancing age.

HISTOLOGICAL STUDIES OF NORMAL GANGLIA

The ganglia which we used as control material for this study were obtained at necropsy in 40 consecutive cases in which death had resulted from various causes. None of the patients had suffered from any of the four conditions which we have considered. We sought the same changes that we had looked for in the various conditions mentioned. Less than half the vessels were normal but the changes which were present were slight, and most of them can be accounted for on the basis of age. The walls of the vessels were slightly thickened in more than 50 per cent

of the subjects and in a few (one-eighth) there was proliferation of the endothelium lining the intima and as in the vascular conditions this was slight much slighter than is constantly seen in cases of severe or even mild hypertension. There was no sign of acute or chronic inflammation or increase in the connective tissue in the ganglia, occasionally the connective tissue was much looser in texture and slight edema was present this was probably the result of local inflammation which was present in several cases. Lymphocyte-like cells were present in small groups but less frequently than in any of the other conditions and this was the only observation which varied from those constantly noted in the ganglia removed in the other cases considered. The ganglion cells themselves showed changes similar in type and degree to those we observed in the other cases. Chromatolysis was present in a few ganglia, and cystic degeneration of several ganglion cells was also seen swelling of the endocapsular cells which corresponded to the vacuolization of the periphery of the cytoplasm of the ganglion cells was common. The most interesting observation was that of pigment in the ganglion cells. The various ganglia were studied the changes noted and the degrees of change recorded without any knowledge of the age of the patient or the condition from which he suffered. The age in the control series was higher than in any other series. The average age in the control series was 46.6 years. More material must be found before definite conclusions can be reached regarding the age at which pigment first appears. The average age of patients whose pigment was graded 1 was 43.7 years the average age of patients whose pigment was graded 2 was 56.9 years, and the average age of patients whose pigment was graded 3 was 64.7 years. There was, as in any control series, a marked variation in the individual cases, but nevertheless a marked tendency for the pigment to increase with age. This has been our observation for many years and coincides with that of others.

GENERAL COMMENT

In comparing the histological observations of the sympathetic ganglia, removed for the

Fig. 1. Cervicothoracic and lumbar sympathetic ganglia removed surgically from cases contained in this series. The lack of uniformity in the anatomical distribution of the ganglia along the sympathetic trunk is well illustrated as well as the tendency for one or more ganglia to be fused.

conditions described with each other and with those of normal ganglia nothing was found to explain the various vascular disturbances. All the changes were within normal limits and most of them can be explained on a basis of advancing age. There was no histological difference between the ganglia removed for the various diseases although these varied much in their clinical manifestations. The blood vessels in the ganglia removed from patients with vascular diseases did not partake of the changes in the blood vessels of the diseased extremities and were similar in most respects to the control vessels. Small collections of lymphocyte-like cells were present in all the ganglia as well as in the control ganglia. These cells closely simulated lymphocytes and differential stains were of little positive value yet it is possible that they represented proliferated endocapsular cells replacing degenerated or disintegrated ganglion cells. In opposition to this possibility is the fact that they were not always enclosed in the capsule which normally surrounds ganglion cells although endocapsular cells surround the dendritic processes

Fig. 2. Marked variation of the degree of endocapsular cell proliferation may be noted. Swelling of some of these cells is present with erosion of their periphery with the formation of peripheral vacuolization. In one place, the proliferated endocapsular cell has replaced the ganglion cell and in another only a small remnant of the ganglion cell is seen, and this is pyknotic (toluidin blue $\times 350$).

of the ganglion cells. These cells were always in groups and not scattered diffusely throughout the ganglia. They were not associated with blood vessels which is frequently the case in inflammation of the central nervous system. Sympathetic ganglion cells are surrounded by a delicate capsule which is covered on the outside by a layer of flattened elongated cells of connective tissue origin and are referred to as ectocapsular cells whereas the inner side of the capsule is lined with a layer of cells which we have referred to as endocapsular cells and to which von Lenhossek gave the name 'amphicytes' and Cajal called 'satellite cells'. The origin of these endocapsular cells is not yet definitely established but we think that they are analogous to oligodendroglia, just as De Castro considers the analogous cells of the ganglia of the spinal nerves a type of neuroglia similar to Hortega's oligodendroglia rather than of mesodermal origin. In this way they simulate the satellite

Fig. 3. Endocapsular cell proliferation in one cell, with vacuolization of the periphery of the cell. In another cell, ectocapsular cell proliferation is demonstrated. These cells are flattened (hematoxylin and eosin $\times 355$)

cells of the central nervous system. Their reaction both in the normal ganglia and in those surgically removed is similar to the acute swelling of the oligodendroglia described by Penfield and Cone, and which have been shown to be analogous to the mucocytes of Grynfeldt. The swollen endocapsular cells of the sympathetic ganglia were surrounded by clear spaces similar to oligodendroglial cells. It is with the greatest difficulty that cell bodies belonging to these cells could be demonstrated even with Hortege's silver carbonate method. Cajal's gold chloride and sublimate method also failed to reveal cell bodies. None of the swollen endocapsular cells contained debris which had an affinity for silver indicative of phagocytic activities so that the indentations in the ganglion cells were not the result of phagocytosis. However mucus stains showed that some at least of the spaces around the endocapsular cells contained a slight amount of thin mucus. This was not constantly present but was seen with sufficient frequency to produce a simi-

larity to the mucocytes which Bailey and Schaltenbrand have shown to be acutely swollen oligodendroglial cells. In only a few ganglia these endocapsular cells appeared to be proliferated (Fig. 2). Even more rarely were the ectocapsular cells proliferated although in the few instances in which it had occurred it was quite definite (Fig. 3). Most of the large cysts which caused compression and frequently complete destruction of the ganglion cells contained abundant and easily demonstrable mucus. Some of the sympathetic ganglion cells had a ragged appearance (Figs. 4 and 5) thus we have referred to as vacuolization considered to be the result of the acute swelling of the endocapsular cells which occasionally contain mucus. This process may become quite pronounced and the vacuolization may produce marked reduction in the size of the cell body, simulating the corroded cells of the spinal ganglia, which have been described by De Castro (Figs. 4 and 5). In none of the ganglia which we have studied had it progressed to the degree described by De Castro, or led to complete disintegration of the ganglion cell. Around most ganglion cells in fixed preparations there is a definite clear space separating it from the cell capsule. This space varies much in different cells, and it appears to us to be an artefact due to shrinkage of the cell during the process of fixation. The presence of pigment granules in the cells of the sympathetic ganglion is recognized by all investigators, and it increases with age so that in elderly persons most cells contain numerous pigment granules. Our study of the sympathetic ganglion cells confirmed the observations of others that the pigment increases with age and that it is made up of two types, the lipochrome or fat containing pigment which stains with sudan III and the fat-free type which has an affinity for silver and is probably a true melanin pigment. Increase in the deposition of pigment in the body during the later decades of life is not limited to ganglion cells of the sympathetic nervous system but it increases in the ganglion cells of the central nervous system and in many other organs. In our study of the ganglion cells of the sympathetic nervous system a definite increase with advancing age

Fig. 4. A group of four ganglion cells, one of which is normal, one shows the effect of the capsular cell proliferation with the vacuolization of the cell body (silver impregnation $\times 700$).

was constantly noted and we feel that this has no connection with the disease process for which the ganglia were removed. Occasionally many bright eosin staining granules are intermingled with the pigment granules. The significance of these eosinophilic granules is not clear. With silver impregnation methods the outline of most ganglion cells appeared normal with their numerous processes extending in all directions into the surrounding tissue and neurofibrils appeared normal (Figs. 4 and 5). Occasionally ganglion cells were compressed by cysts which we have noted in consideration of the various cases and even the remnants of the compressed cells had a strong affinity for silver nitrate (Figs. 4 and 5). The same silver impregnation methods demonstrated the fact that axis cylinders were present in normal numbers and they seemed to be normal in outline and regular in their course and distribution.

These various observations lend support to the conclusion which has frequently been advanced, that the noxious agent causing the vascular diseases for which operative relief

Fig. 5. This ganglion cell shows one large vacuole encroaching on its cell body. The nucleus of the swollen endocapsular cell which caused the vacuole, is visible (silver impregnation $\times 840$).

has been instituted does not act on the sympathetic ganglia removed. Since the removal of the sympathetic ganglia leads to improvement of the blood supply to the affected limbs it would seem that the ganglia act simply as relay stations for impulses from higher centers where the disease originates.

STUDIES ON BRONCHIAL OCCLUSION BY THE METHOD OF ADAMS AND LIVINGSTONE¹

ALFRED BLALOCK M.D. AND W. M. RAYMOND M.D. NASHVILLE, TENNESSEE

THE absence of a safe and satisfactory method of occluding large bronchi has been a great handicap to the development of surgery of the lungs. The recent important experimental work of Adams and Livingstone in which bronchi were occluded by the local application of a 35 per cent solution of silver nitrate has possibly supplied a method which may be of vast benefit in the treatment of patients with pulmonary disease.

In attempting to repeat the work of Adams and Livingstone (2) in order to satisfy our own curiosity several difficulties were encountered that are being reported in this paper. In addition studies were performed under several experimental conditions that have not been investigated by them.

Dogs and cats were employed as the experimental animals. A 35 per cent solution of silver nitrate was used in all experiments. A small piece of cotton that had been placed on a bronchoscopic forcep was saturated with the silver nitrate and the application to the bronchus was made through a bronchoscope. Morphine was used as the anesthetic for the dogs and nembutal for the cats. Ether anesthesia unaccompanied by the injection of atropine was tried in some of the experiments but there was such a profuse secretion into the bronchus that the silver nitrate did not exert its effect.

Cats were used as well as dogs because the mediastinum of the cat is more rigid than that of the dog. Attempts were made to use rabbits which have a still more rigid mediastinum but due to the small size of the trachea, these attempts were abandoned. In the first group of experiments on both dogs and cats the death rate was high. Seven of the first 10 dogs died and 8 of the first 10 cats lived only a short while. Death frequently occurred within 48 hours following the application of the silver nitrate and it was usually associated with hemorrhage. The animals which died several days following the application showed at

autopsy a pneumonic consolidation of the lobe the bronchus of which had been cauterized. A similar appearance was noted in one dog that lived 15 days. In one dog that was killed 55 days following the application of the silver nitrate there were several rather hard areas in the lobe in question the neighboring bronchi were dilated and contained mucoid material. The rest of the lobe was air containing. In a cat that died 26 days after the application part of the lobe the bronchus of which had been cauterized was completely atelectatic while the remainder showed a pneumonic consolidation. In several of the animals one or more of the lobes were completely atelectatic as has been described by Adams and Livingstone. A photograph of the lungs of a cat which shows complete atelectasis of the left side is given in Figure 1. This animal was killed 27 days following the application of the silver nitrate.

The mortality rate has been very much lower in our subsequent experiments and we believe that the high rate in the earlier studies was due partially to the fact that we did not rid the cotton pledgets of the excess of silver nitrate. It seems likely that the pressure of the pledget against the bronchus squeezed some of the solution out of the cotton and allowed it to escape into the smaller bronchi.

Emboic lung abscesses were produced in 10 dogs by the method described by Holman, Weidlein and Schlueter. Two weeks later a 35 per cent solution of silver nitrate was applied to the bronchus of the affected lobe. Three of the dogs died several days following the application. The 7 remaining dogs were subjected to autopsy 6 weeks later. A residual abscess was found in 4 of the 7 dogs. The bronchus of the diseased lung was not occluded in any of the 7 dogs. In 2 animals in which the abscess was in the right lower lobe, the bronchus of the right accessory lobe was found to be occluded and the lobe was completely atelectatic while the bronchus of the diseased

Fig. 1. Heart and lungs of a cat showing complete atelectasis of left lung following the application of silver nitrate to the bronchus.

Fig. 2. Showing complete atelectasis of right accessory lobe. The right lower lobe is air containing and a small residual abscess is to be seen.

lobe was not occluded and the lobe was not atelectatic. A small residual abscess was present in the lower lobe in these 3 instances. The accompanying photograph (Fig. 2) shows the atelectatic accessory lobe and the non-collapsed right lower lobe of one of the dogs. A small abscess can be seen in the right lower lobe.

Adams (1) has recently found that the application of silver nitrate to the bronchus of a lobe containing an experimentally produced pyogenic abscess usually causes delay in the healing of the abscess. Our findings in this respect are confirmatory of his.

Intrapulmonary disease in the human is frequently associated with thickening and stabilization of the mediastinum, or adhesions between the visceral and parietal layers of pleura, or both. The condition of affairs in the chest of the normal dog is quite different and particularly so since the dog has an extremely thin and easily movable mediastinum. In order to try to render the chest of the diseased human and that of the dog more nearly comparable two types of procedures were performed. In 5 dogs, a portion of one of the lower ribs was removed and the right lower lobe was sutured in a number of places to the chest wall and the visceral pleura of the lobe was painted with mercurochrome. Two of the dogs died of empyema. After the incisions had

healed in the remaining dogs, silver nitrate was applied to the region of the right lower lobe bronchus. Six weeks later the animals were killed. There were fairly firm adhesions between the right lower lobe and the chest wall. The bronchus to the right lower lobe was not occluded. In one of the animals, the bronchus to the right accessory lobe was occluded and the lobe was atelectatic. In experiments on 4 dogs, an intercostal incision was made on the right side and the mediastinal pleura was painted with 3.5 per cent iodine. Two of the animals died of empyema. After the incisions had healed, silver nitrate was applied to the right lower lobe bronchus. The two animals were sacrificed and autopsied 6 weeks later. The mediastinum of each was thickened but was not absolutely fixed. There was no bronchial occlusion in either of the animals. We do not believe that these experiments are highly significant because the number of animals is small and because repeated applications of the silver nitrate would probably have resulted in occlusion.

Attempts were made to produce bronchial occlusion in puppies approximately 6 weeks old for the purpose of studying the alterations in the lungs after the dogs reached their full development. The mortality rate in these experiments has been very high. Most of the animals had severe paroxysms of coughing

Several of the puppies lived less than a week following the application of the silver nitrate. Death of 3 of the animals occurred 4 weeks, 5 weeks, and 6 weeks following the application of the silver nitrate. Clear fluid was present in both pleural cavities of 2 of these. There was complete atelectasis of the left lower lobe of one of the puppies while the 2 remaining showed a pneumonic consolidation without bronchial occlusion.

The output of the heart and the maximum and minimum blood pressure were determined in experiments on 3 dogs before and after the production of atelectasis of the left lower and the right accessory lobes. No significant alterations in either the cardiac output or the blood pressure were found. The occlusion of a greater number of bronchi would probably be associated with changes in the cardiac output and blood pressure.

SUMMARY

The method of Adams and Livingstone of producing bronchial occlusion by the local application of 35 per cent silver nitrate has been employed in experiments on dogs, puppies and cats. The extremely high death rate in the early experiments was probably due partially to the use of an excess of the silver nitrate solution. The dangers were lessened but not entirely eliminated by observing this

precaution. When the attempts at bronchial occlusion were successful the alterations in the bronchus and in the atelectatic lobe of the cats and puppies were similar to those that have been described by Adams and Livingstone for the dog.

Attempts at occlusion of the bronchus of a lobe that contained an embolic pyogenic abscess were unsuccessful. The abscess did not alter the ability of the silver nitrate to close the bronchus of an adjacent lobe. In the several experiments in which adhesions between the visceral and parietal layers of pleura had been produced and in those in which a thickening of the mediastinum had been caused by irritants the single application of silver nitrate did not result in an occlusion of the bronchus. The occlusion of the left lower and the right accessory lobes of dogs did not cause significant alterations in the cardiac output and blood pressure.

CLINICAL SURGERY

FROM THE GRAND RAPIDS (MICHIGAN) CLINIC

SURGICAL MANAGEMENT OF LIP MALIGNANCIES

FERRIS SMITH A.B. M.D. F.A.C.S., GRAND RAPIDS, MICHIGAN

THE initial small malignant lesions about the lips are simply and effectively managed either surgically or by some other destructive agent. The larger more advanced lesions, which do not require destruction of more than one third of the lip may be removed and the lip repaired without the introduction of foreign tissue.

Lesions requiring destruction of more than one third and possibly the total lip have been less boldly and frequently badly managed because the attendant had no satisfactory technique for a repair of the surgical defect.

Few if any of the operations described in texts for large partial or total lip reconstruction should ever be employed. Practically all of these operations contemplate the use of full thickness cheek flaps which are cut without regard for the muscles of expression about the mouth, or for blood and nerve supply. The included muscle atrophies in most instances and supplies only a scar filling which is without function.¹

Methods of reconstruction should be limited to those that conserve all function remaining after the lip destruction. frequently it is possible to restore the major function in the repaired part. It is never necessary to cut into the musculature about the defect. An entire upper or lower lip may be lined and covered from the vicinity of the defect with a minimum of visible scar. The cosmetic result under such circumstances will, obviously approach as near the normal as is possible in any surface repair.

Confidence born of the certainty of such restoration, will permit both the patient and the physician to attack the problem boldly and with greater hope of a successful solution.

SMALL LESIONS

The amount of tissue removed is determined by the size and character of the lesion. The lines of excision should be slightly curved so that

approximation will result in a small elevation of the lip border at the line of suture. This elevation prevents the formation of a notch in the lip border as the result of linear scar contraction.

LARGE LESION WITH AND WITHOUT METASTASES

The management of these lesions is completed in 3 stages: first, destruction of the lip lesion with or without block dissection of the neck; second, reconstruction of the lip; third, cosmetic corrections.

The first stage requiring block dissection, is performed under general anesthesia, utilizing either avertin or ether vapor. Those cases requiring only dissection of the submental and digastric triangles are operated upon under local anesthesia supplemented with sodium amylal or nembutal.

The lines of skin incision should be placed at least 1 centimeter on either side of the palpable borders of the lesion. These incisions are carried from the free margin of the lip to the buccal sulcus or as far beyond as the lesion requires. In those cases in which the lesion involves only the lip, the excision is completed by carrying a horizontal incision along the sulcus about 3 to 5 millimeters from the fornix.

The management of the borders of this excision must anticipate the reconstruction of the lip. To accomplish this, flaps for a lining to replace the excised mucosa for the outer skin covering and for the vermilion free margin, must be so planned that ample material enjoying an adequate blood supply is available.

The blood supply of the lining flap, which will be reflected from the skin adjacent to the angle of the mouth, must come from the buccal mucosa and the muscle bordering the incision. Consequently the mucosa on this edge must be undermined and accurately approximated to the skin with fine, closely placed horsehair sutures. This produces a minimum of scar and a maximum blood supply. This blood supply is usually

¹Forde Smith, Nelson: *Reconstructive Surgery*

sutured with horsehair to the free margin of the reflected lining flap and also to the mucosa in the angle of the mouth.

adequate but it can be guaranteed by outlining partially undercutting and reapproximating this skin flap at this stage (A Fig. 3)

The mucosa bordering the edge of the lip remnant is similarly undercut and sutured. This mucosa will be utilized to form the free vermilion border of the reconstructed portion of the lip (C Fig. 4)

The skin bordering the excision—chin or face and nose in the case of a lower or upper lip—is undercut and accurately approximated to the mucosal remnant along the buccal sulcus.

These suture lines are painted with compound tincture of benzoin until they are thoroughly sealed. A strip of gauze is fastened with collodion

to the cheeks on either side to limit movement. No other dressing is applied.

The flaps for the lining *A* and the covering *B* are outlined. They may be raised and sutured in their original locations at this time if the blood supply is questionable. The blood supply, however, is usually excellent.

The mucous membrane on the incised edge of the lip remnant is removed between two parallel incisions placed 1 centimeter apart. One incision is carried down its union with the skin and the other through the mucosa on the posterior surface of the lip. Its blood supply is formed by the mucosa on the free margin of the lip and a broad portion of mucosa posteriorly. This flap *C* held

Fig. 6 A, Perforating carcinoma creating a pathological harelip. B, Appearance of the lip 3 weeks after excision. The removal of the lesion included the tissue bordering the nasal ala. The defect has been closed by loosening the cheek tissues from the underlying bone and suturing to the base of the nose. C, Appearance of the lip 6 years after operation.

Fig. 7 Carcinoma of the mid-portion of the lower lip. A, Appearance weeks after excision of the lip and dissection of both digastric and submental triangles.

D The reconstructed lip. B and C, Demonstration of the muscular action which is now possible in the reconstructed mouth.

on the sharp hook, will form the vermillion border of the reconstructed lip.

The skin flap (A Fig 3) carrying underlying fat, is turned from the face on a "hinge" and sutured to the incised margin of the mucosa on the posterior surface of the lip remnant.

The covering flap (B Fig 3) is incised and elevated with the underlying fat.

The skin of the face on either side of the defect resulting from elevation of the covering flap (B Fig 3) is freely undercut and approximated with horsehair sutures. The approximation of these skin edges adds two-thirds of the width of the flap to its length.

The covering flap (B Fig 3) is rotated 90 degrees to cover the lip and the defect left by reflection of the lining flap (A Fig 3). The opposing skin edges are sutured with horsehair.

The anterior edge of the mucosal flap (C, Fig 4) is sutured to the free edge of the covering flap with horsehair.

The tent, (D Fig 5) created by the rotation of the covering flap (B Fig 3) is adjusted by the removal of excess skin and suture. This should not be done sooner than the twelfth day because of possible damage to the adequate blood supply of the transplanted flap prior to this time. Any other cosmetic defects are corrected at this period.

The suture lines about the mouth are painted with compound tincture of benzoin and those on the face and neck covered with a gauze dressing wet with alcohol.

All skin stitches are replaced on the second or third day with gauze collodion supports which are maintained a minimum of 10 days.

The lining of the lip which is formed by reflection of the skin from the face is annoying to male patients because of the growth of hair. This can be replaced after 60 days with normal mucous membrane from the cheeks. The repair is effected by multiple excision. Approximately one half the skin can be removed at the first stage and buccal mucosa advanced to fill the defect. Sufficient relaxation of the mucous membrane will again

occur at the end of 4 to 6 weeks to permit the excision of the remaining skin.

It is sometimes advisable to utilize flaps from both sides of the mouth in the construction of an entire lip. When this method is followed a long covering flap and shorter lining flap should be cut on one side and the reverse procedure practised on the opposite side. This will place the junction line of the covering flaps at a different point than the union of the lining flaps and prevent a depressed adherent scar line.

This plan of management permits the boldest attack on the local lesion and, at the same time provides a method of repair which is highly satisfactory from both functional and cosmetic standpoints.

FROM THE KASR EL-AINY HOSPITAL CAIRO

A TECHNIQUE OF TUBO-UTERINE ANASTOMOSIS (IMPLANTATION) IN INTERSTITIAL AND ISTHMIC OCCLUSION

AHMAD SILAFEEK M.B. B.S. (LOND) F.R.C.S. (ENG) CAIRO, EGYPT
Gynecological and Obstetric Surgeon to Kasr El-Ainy Hospital

TUBAL implantation if it should at all serve the object for which it is done must be planned so as to give the utmost uterine security both during pregnancy and labor. It should not disturb the normal anatomy by injuring the musculature of the uterus or its cornual sphincters.

It should as well aim at conserving the salpingo-uterine continuity permanently. Mere implantation into the uterine cornua and the bringing together of uterine and tubal mucosa (end to end union) is insufficient. Even if permanent permeability is thereby attained the line of junction might become constricted which would defeat our object.

INDICATIONS AND CONTRA INDICATIONS

The choice of cases for implantation cannot usually be definitely decided beforehand as we cannot foretell whether or not sufficient tubal length will be available. It is therefore clear that abdominal exploration is necessary even if tubal implantation is not found feasible. We would then be able to liberate adhesions, resect any diseased part of the ovary or the tube or correct the uterine position if any of these conditions is present.

Tubal implantation is indicated under the following circumstances:

1. In the presence of sterility with interstitial blockage that shows no evidence of any actual adnexal inflammation.

2. Or in cases in which there had previously been adnexal inflammation which had been relieved and there had been no recurrence for a sufficiently long period. I.e. about a year or a time.

Pre-operative hysterosalpingography should always be done preferably not less than a week

beforehand. A course of treatment with tampons and douches is done afterward to alleviate any irritation caused by the manipulations or the lipiodol. Implantation would naturally have no place in cases that show definite uterine infantilism or atrophy or in cases of ovarian hypofunction whether primary or secondary to the chronic pelvic inflammation and adhesions. Restoration of anatomical and functional permeability fulfills no object in such cases.

STEPS OF THE OPERATION

The usual vaginal toilet is carried out.

The cervix is dilated to the size of a No. 8 Hegar dilator so that a Bonney insufflator can be inserted without any leakage. The insufflator is left *in situ*.

Abdominal operation. The adhesions are liberated. The uterus and adnexa are delivered through the wound. A sound with a bulbous end is introduced into the abdominal opening of both tubes to determine the extent of their patency and to obtain a clue as to where we should cut the tube across—that is at its innermost permeable point (Fig. 2). We should require at least 6 centimeters of fallopian tube (ampullary and isthmal) for efficient utilization.

The isthmal tube which is the part usually blocked, is liberated from its mesosalpinx up to the cornu where it merges into the short interstitial part (Fig. 3). At this junction and with a conscious preservation of the cornu in its entirety a circular incision through serosa and muscularis is made until we encounter the fibrosed impermeable core that remains of the interstitial mucosa. This core with its continuation in the interstitial tissue is patiently and gently dissected

Fig. 9. Later step in procedure.

out from the cornual musculature with a fine knife. If it cuts through as frequently happens the whitish spot that represents its continuity serves for further dissection until we open into the cone of endometrium that lines the uterine angle. The dissection is made much easier by the utilization of the Bonney or other insufflator to distend the uterine cavity and thus to bring the endometrial apex of the cornu farther out. The opposite side is treated in a similar manner and a small dilator is inserted in the opening already made when the insufflator is again manipulated. By this patient dissection we are able to conserve the muscular integrity of the cornu (Fig. 4).

The fine tracts left are then gradually sufficiently dilated by means of the Fenton dilators the dilators passing through both ends at the same time to admit the passage of a whole thickness of the tube (Fig. 5). Two catgut sutures are passed through the whole thickness of the inner ends of the cut tubes on both sides and are tied (Fig. 6). The sutures are then passed through the eyes of two rather long probes which are guided, in opposite directions through cornu uterine fundus the other cornu to the opposite tube and out of the abdominal ostium together with the sutures which are delivered out of the same tract (Fig. 7). The sutures are then pulled upon in opposite directions with the result that the inner part of each cut tube is telescoped entirely into the respective cornu to the degree required (Figs. 8 and 9).

In cases in which the tube on one side is found to be totally disorganized or its patent part so short as not to be utilizable the sutures placed on the cut end of the other effective tube are made to pass on a needle through the cornual hole and pierce from within outward the corresponding walls of the fundus about its middle line (Fig. 10). These sutures are pulled upon sufficiently to telescope the required length of whole tube inside the cornu.

Interrupted seromuscular sutures are inserted to unite cornu to tubal wall and thus firmly anchor it in position.

Tubo-uterine continuity is thus assured by these steps and a sufficient amount of the entire tube is invaginated into uterine cornu. The trans-uterine and tubal lengths of catgut left *in situ* further help to secure the permanency of this continuity as they remain there for some 40 days. Sterile oil or bomenol if available is put in to prevent adhesions. After the operation the uterus is usually in a good position and the posi-

Fig. 10 Technique in case one tube alone is available for implantation.

FROM THE KASR EL-AINI HOSPITAL CAIRO

A TECHNIQUE OF TUBO-UTERINE ANASTOMOSIS (IMPLANTATION) IN INTERSTITIAL AND ISTHMIC OCCLUSION

AHDIAD SHAFEEK M.B. B.S. (Lond.) F.R.C.S. (Eng.) CAIRO EGYPT

Gynaecological and Obstetric Surgeon to Kasr El-Aini Hospital

TUBAL implantation if it should at all serve the object for which it is done must be planned so as to give the utmost uterine security both during pregnancy and labor. It should not disturb the normal anatomy by injuring the musculature of the uterus or its cornual sphincters.

It should as well aim at conserving the salpingo-uterine continuity permanently. Mere implantation into the uterine cornua and the bringing together of uterine and tubal mucosa (end-to-end union) is insufficient. Even if permanent permeability is thereby attained the line of junction might become constricted which would defeat our object.

INDICATIONS AND CONTRA INDICATIONS

The choice of cases for implantation cannot usually be definitely decided beforehand as we cannot foretell whether or not sufficient tubal length will be available. It is therefore clear that abdominal exploration is necessary even if tubal implantation is not found feasible we would then be able to liberate adhesions resect any diseased part of the ovary or the tube or correct the uterine position, if any of these conditions is present.

Tubal implantation is indicated under the following circumstances:

1. In the presence of sterility with interstitial blockage that shows no evidence of any actual adnexal inflammation.

2. Or in cases in which there had previously been adnexal inflammation which had been relieved and there had been no recurrence for a sufficiently long period i.e. about a year's time.

Pre-operative hysterosalpingography should always be done, preferably not less than a week

beforehand. A course of treatment with tampons and douches is done afterward to alleviate any irritation caused by the manipulations or the lapelod. Implantation would naturally have no place in cases that show definite uterine infantilism or atrophy or in cases of ovarian hypofunction whether primary or secondary to the chronic pelvic inflammation and adhesions. Restitution of anatomical and functional permeability fulfills no object in such cases.

STEPS OF THE OPERATION

The usual vaginal toilet is carried out.

The cervix is dilated to the size of a No. 8 Hegar dilator so that a Bonney insufflator can be inserted without any leakage. The insufflator is left in situ.

Abdominal operation. The adhesions are liberated. The uterus and adnexa are delivered through the wound. A sound with a bulbous end is introduced into the abdominal opening of both tubes to determine the extent of their patency and to obtain a clue as to where we should cut the tube across—that is at its innermost permeable point (Fig. 2). We should require at least 6 centimeters of fallopian tube (ampullary and isthmal) for efficient utilization.

The isthmal tube which is the part usually blocked is liberated from its mesosalpinx up to the cornu where it merges into the short interstitial part (Fig. 3). At this junction, and with a conscious preservation of the cornu in its entirety a circular incision through serosa and muscularis is made until we encounter the fibrous impermeable core that remains of the interstitial mucosa. This core, with its continuation in the interstitial tissue is patiently and gently dissected

ADVANTAGES

The advantages of this operation which we have been doing for the last 3 years at Kasr El Ainy, Ilc, primarily in the maintenance of the muscular integrity of the uterus. The object of the operation is to reinstate tubo-uterine permeability in an effort to overcome this cause of sterility. And it is our belief that a uterus treated as we have described, with the musculature left intact, is better fitted to stand the strain of pregnancy and labor than is a uterus in which the cornua have been incised, cored-out or resected.

The advantage of the special way by which the tube is implanted in order to secure permanent continuity in its normal direction is evident.

There are two theoretical drawbacks to methods of operation in which the tube is not implanted in its natural site namely (1) the fertilized ovum is then implanted lower and (2) during periods of muscular atony the menstrual fluid may easily be regurgitated and this might lead to the occurrence of pelvic endometriomata.

The appended hysterosalpingograms demonstrate the integrity of the musculature of the cornua of the uterus. They were taken immediately after the injection of the lipiodol, while

screening. The conformity of the uterine cornua with the normal shape is well seen.

My thanks are due to Prof. R. S. Dobbin for encouraging me to make this study and for allowing me to use the French literature in his possession to my colleague Dr. H. Sobhy, obstetric tutor who has done the operation himself several times to Drs. Ahmed Marey and Hussein Erlan for the radiograms and to Mr. Strelakovsky the artist to the Faculty for the execution of the drawings.

Fig. 3. Complete immobilization of arm. Advancement of pectoralis major and latissimus dorsi. Thick split grafts only possible method of covering defect. A, Arm grown solid to body with excessively thick scar over entire side. Deep dirty sinus running high toward axilla, $3\frac{1}{4}$ years

after burn. At the first operation the sinus was simply opened and then scirrhous packs were kept on the raw area. At the second operation the contracture was spread widely but the arm would not come up satisfactorily. In consultation with Dr. C. H. Crego it was decided to ad-

Fig 3A

Fig 3B

Fig 3C

vance the pectoralis major and latissimus dorsi upward on the chest wall, and this was done without disturbing the nerve supply and without exposing the contents of the axilla. The muscles were anchored with catgut and the arm could be raised to the vertical. It was necessary to stop the procedure, and the area was dressed with acriflavine gauze. At the third operation (done 48 hours later) the entire area was covered with thick split grafts and the arm fixed with the dressing as described in Figure 1. Accurate measurement of the skin removed from the thigh showed five large areas and one small one, and the total area denuded 173 square inches (1,081 square centimeters). These grafts "took" successfully and good function and free movement up to about 105 degrees abduction were obtained.

At the fourth operation the contracture was opened low across the axilla, and one was opened just above the elbow. The resultant defects were covered with thick split grafts from the thighs. Three denuded areas on the leg measured 48 square inches. Total for both operations of 221 square inches (1,381 square centimeters). The final surface area covered as measured with a paper pattern shows less than one-half this amount. This is not an accurate measurement of field contracture, but rather an index of the large amount of graft one should have to cover one of these areas adequately.

B, C, and D There is practically complete function, and the power of the pectoralis major and latissimus dorsi has been maintained (see Fig 4). In D along the posterior edge, note the small triangular inset of graft that allows important relaxation. The thighs show the rather inconspicuous scars of the thick split grafts, and in time another "crop" of grafts can be cut from these same areas to cover the heavily scarred flank if it gives too much discomfort. In B the scars of a few small deep grafts (done before entry to this service) can be seen.

This boy is an ideal type from which to cut thick split grafts by means of the suction retractor. The thighs are large and firm, and not too muscular. In a smaller child with a deformity of comparative size it might be a difficult matter to get adequate grafts for the covering of the defect.

Fig 4. Physiotherapy. Function. Same patients as shown in Figures 3 and 7 in the gymnasium of the Physiotherapy Department at Shriners Hospital. It seems that postoperative stiffness and even second contractures in these cases may be easily overcome if a will to help themselves is instilled in the patient and simple equipment is supplied for exercise and play. A trapeze hung in a transept of the hospital or home may suffice. Massage and baking and baths are seldom necessary if the restoration has been adequate and the patient is able to exercise. Function to be complete should, of course, permit complete motion of the arm, but in some instances, if the arm is gotten to above right angles by one operation, it may be difficult to get the patients to submit to further procedures because they do not feel that they have enough deformity to warrant it.

Fig 5. Comparison of full thickness and thick split grafts. Breast function and position. A Arm grown firmly to side, complete destruction of axillary skin, widespread loss on chest, 1 year after burn. B The deformity was released and the defect covered with a single full thickness graft that included almost the entire lower abdominal skin. C About 1 year later some limitation of motion remained along the anterior axillary fold. This area was opened, and the defect covered with thick split grafts to give the result shown here taken still a year later. At this time it was impossible to distinguish the full thickness from the thick split graft. The white area is spontaneous healing that has occurred over areas of fairly deep loss. The breast may be elevated out of position, and, if possible, the original operation should correct this by relaxing it and grafting the defect. It may occasionally be pulled down if there has been heavy scarring over the flank and abdomen, and a separate operation and graft may be necessary for elevating it.

If the nipple area has been destroyed and there is heavy scarring over the breast tissue, it is our belief that the gland tissue atrophies and never regains its function. We have never seen any trouble with the breasts whether just heavily scarred or whether the nipple area itself has been destroyed, but pregnancy has not occurred in any patients of this series, and so the observations are not complete.

SUMMARY OF CASES

Type and sex	Duration of lesion healed or unhealed	Type of graft used	Flap or graft across apex of lesion	Function, scars grafted No. of operations
3	6 mos Healed Extreme deformity	Full thickness	Graft No flap available	Both folds, arm, apex. Complete function One operation
5	4 yrs Healed	Full thickness	Graft No flap available	Both folds, arm, apex. Complete function. One operation
6	yr Healed	Full thickness	Graft. No flap available	Both folds, arm, apex. Complete function One operation
6	1 yr Unhealed because of added X-ray burn	Full thickness	Graft. No flap available	Anterior fold, arm and chest to let breast down in place. One operation
6	10 mos Healed	Full thickness	Flap from incision for apex	Both folds, arm, chest. Not complete elevation but only one operation done
5	6 mos Healed Marked deformity and itching	Full thickness	Graft No flap available	Both folds, arm, chest, and apex. Complete function. One operation
	6 mos Widespread keloid and itching	Full thickness and thick epic on cover partial loss of full thickness	Local flap	Abduction gotten from 5 to 105 degrees Secondary operation refused
	yr Unhealed Sealed growth to side	Full thickness followed 1 or yr by thick epic	Graft No flap available	Both folds, arm, chest, apex. Complete elevation operation
	yr Healed	Full thickness	Graft N flap available	Anterior fold and apex. Complete function One operation for each side
9	mos Fleury keloid, extreme itching	Full thickness right and left	Neither necessary	Anterior folds and chest. Complete function and flap operation necessary on left
	3 mos Marked deformity from dedication of the rad cervical vertebra associated at the time of the burn Neck and axilla unhealed	Thick split	Anterior fold, apex Breast let down with thick split grafts	Function perfect. One operation, breast down in normal position. Vertebra reduced by Dr. Tamm Branson
6	yr Healed Had many small deep grafts, with healing but almost correction of deformity	Thick split	Local flap	Anterior fold, chest, arm. Two operations Complete function
18	mo Whole chest and right axilla one painful ulcer	Thick split	Neither necessary	Whole anterior chest wall. Anterior fold 1 operation. Complete function
3	mos Unhealed Very widespread, body chest, neck, arm	Thick split	Local flaps	Arm, chest, anterior fold. operations Complete function
	4 yrs Good etc Only slight limitation of function Had operations that only scarred the webs further	Thick split	Local flaps	Chest, anterior fold, arm. One operation Complete function
3	Several yrs Healed	Thick split	Local flaps	Chest, anterior fold, arm. One operation Complete function
13	6 1/2 yrs Electric burn. Extreme deformity about elbow but with only slight web in both axillary folds	No grafts necessary	Local flaps	Anterior fold apex flap operation. One operation. Complete function
3	yr Deformity both folds, itching and puckering	No grafts necessary	Local flaps	Both folds and apex flap operation. One operation. Complete function
3	1 1/2 yrs Arm bound to side. Wide scarring	N grafts necessary	Local flaps	Both folds and apex flap operation. One operation. Complete function
6	yr Several operations Almost relief of deformity	No grafts necessary	Local flaps	Anterior fold apex flap operation. Complete function
3	1 1/2 yrs Arm solid to body with deep dirty pockets. Extremely thick scar over whole side of body	Thick split	Thick split grafts and scar flap from the chest for axil fold. N de- fect flap available	Both folds, apex, arm, chest, and back. Pectoralis major and latissimus dorsi taken entirely from these regions and advanced toward axilla. 1 operation. Over one square inches of skin used. Complete function obtained
9	1 yr Healed	Thick split	Thick split. No flap available	Anterior fold, chest, apex, arm. operations Complete function

SUMMARY OF CASES—Continued

Types are in years	Duration of lesion healed or unhealed	Type of graft used	Flap or graft in axilla	Function areas grafted No. of operations
1 7	2) none Unhealed	Thick split	Thick split No flaps available	Anterior fold, arm, apex best One operation Complete function
1 4	none U healed	Thick split	Thick split No flaps available	Flank, anterior fold, arm, chest One operation Complete function
15	3 yrs.	Thick split	Thick split No flaps available	Both folds, per, best 1; let breast down flank One operation. Complete function
1 5	6 mos. Extreme deformity, right, not left Back heavy keloid. Child unable to protect self in falling	Thick split	Thick split grafts. Tried 1 turn flaps but they were not sufficient	Both folds, per, arm, chest Both right and left sides. Three operations. Practically complete function
	3 yrs. Healed. Arm brown to side	Thick split	Thick split grafts. No flaps available	Both fold, arm, chest, per One operation Complete function
1 8	37 Healed. Extreme deformity Dislocation cervical vertebrae 1 time of burn	Thick split	Thick split grafts. No flaps available	Both folds, arm, chest, apex One operation Complete function. Also had reduction of dislocation by Dr. Theo. Brooks
1	7 yrs. Still ulcerated in one per. Had 3 operations that did not relieve the deformity and that ruined most of the donor arm for getting graft	Thick split	Thick split grafts and local flaps	Both folds, per, arm, chest Two operations Complete function
7	10 wk. Very undernourished severe burn Cleaned up for operation in salt bath and with dry heat	Thick split	Thick split grafts. No flaps available	Both folds, apex, chest, flank 3 operations Complete function
5	6 mos. Heavy scar and painful keloid	Thick split	Local flaps	Grafts, arm, both folds, best. One operation Complete function
7	4 mos. Unhealed. Had one unsuccessful graft elsewhere	Thick split	Local flaps	Grafts, arm, both folds, chest 3 operations Complete function
4	6 yrs. Electric burn. Extremely heavy scarred kelatosis, and discomfort U healed after 6 yrs. Macroscopic diagnoses: epithelioma cell carcinoma	Thick split	Grafts in per. Flaps from front and back folded round arm	Grafts, chest, back, arm, both folds, apex operations. Function almost normal. B. breast blended by removal of cartilages that occurred over flank
7	4 mos. Unhealed. Extreme deformity pain, tickling, and contracture	Thick split	Grafts No flaps available	Grafts, flank, abdomen, both folds, per, arm Arm free but repair unsatisfactory
4	4 mos. U healed	Thick split	Grafts No flaps available	Arm free but repair unsatisfactory operations

NOTE.—The term apex is used to designate the uppermost part of the axillary fossa as seen from the outside, and not as the anatomical apex of the inside of the axilla.

The Type indicated in Column "One" is for convenience in classification of the deformity.

Type 1. Heavy local scar with binding or direct growth of the arm to the side.

Type 2. Heavy scar or keloid formation over the chest, back or flank, involving one axillary fold and possibly the per of the axillary fossa.

Type 3. Web formation of one or both folds.

Fig. 6. Thicknesses of skin grafts. Shows relative thickness of Oiler Thiersch and thick split grafts taken from the inside of a man's thigh. There is a fair thickness of derma attached to the thinner Oiler Thiersch graft, and we have found that even thin grafts are rarely cut through or above the papillary layer as is the rather prevalent idea. They are usually cut just below the papillary layer and the bleeding that follows is from the derma rather than from the papilla. The thick, split graft does not look as thick as might be expected. This, however, was cut through a low level of the derma, but the derma itself was not very thick. This graft roughly includes about three-fourths of the thickness of the derma.

The thickness of the derma varies in different parts of the body on different people, in different ages, and in the two sexes. On the back the epithelium is very thin, but the derma is so thick that the growth of full thickness grafts taken from it is questionable.

Fig. 7A

Fig. 7B

Fig. 7C

Fig. 7D

Fig. 7. Wide chest, neck, and arm involvement. Local results of and scars of donor area of pinch grafts. A, Complete healing with the aid of pinch grafts one year after burn. There has been wide destruction over the chest, and the breast and nipple are entirely destroyed. The arm is held in by the bridge of scar tissue and grafted surface from the chest. B, This web was opened and no tissue was excised except the ulcerated edge. There was marked immediate retraction of the flaps and the large defect was covered with thick split grafts. A small graft was put in at a second operation when the neck was grafted. Full range of motion has been gotten (see Fig. 4). C, The wide degree of retraction following a simple opening incision is seen by the line of old pinch grafts on the arm, and the line of them far over on the chest. Before operation, as seen in Figure 7A, these grafts were all in the same area over the anterior fold. D, Scars of pinch, or small deep grafts done elsewhere after 1 year's time. Scar of thick split graft after 3 months on inside of right thigh.

Fig. 8. Utilization of both sides of a web. A Patient with burn scars of 16 years duration. The limitation of motion of the arm was not bothering the patient at all, and

he sought treatment only because the limitation from the web about the elbow interfered with his work. At operation the axillary web was split in two as outlined, and, without the excision of any surface tissue at all, the retraction of the scarred tissue (which was perfectly soft) was so great that the grafts outlined in C were needed to close the defect. At the same time the web from the arm to the forearm was split and all of it utilized in the closure, but here also it was necessary to use a graft to close the defect, and the graft healed in better than the flaps. Flaps of scar tissue cannot be cut very large or very thin without damaging their vitality. In this case it seemed improbable that grafts would be necessary but on opening the webs there was immediate retraction of the flaps. It is best not to put any tension on these flaps, and this point is emphasized here by the evident looseness of the skin around the elbow in C. In 4 cases out of the series of 35 good enough flaps were gotten so that no grafts were necessary. B, Shows relief of contractures in the axillary fold and in the cubital fossa. C, Grafts outlined. Note the different degree of pigmentation of the grafts—white on chest where it is stretched, dark on arm where all surrounding skin is lax.

Figs. 9B and 9C.

Fig. 9. A Plaster-of-paris cast to support arm. This type of fixation is not necessary and may even be detrimental if there is slipping or twisting of the body inside the cast. B and C, Fixation with a folded bed pad incorporated in the external layers after a firm sea sponge pressure dressing has been applied. This type of fixation is more

comfortable, much more easily applied and with it the patient can sit up without support and be out of bed. It is also much less expensive. The pad is folded in three or four layers and bound firmly on and held with several strips of adhesive. Most of the time the arm should be supported with extra pillows.

surfacing the raw areas the arm being fixed in abduction.

6 The use of large split skin grafts in sufficient number is a simple and almost universally applicable plan of surfacing these areas.

In the treatment of deep burns about the arm and shoulder free movement is the ultimate objective and the earlier this can be made the dominant note the better. With the general condition comfort and morale of the patient all being cared for the most important step in a recent burn is early complete resurfacing of the denuded area. This will shorten invalidism and lessen or prevent further fixation by the scar that occurs with spontaneous healing (Fig. 1).

During the period devoted to general pre-operative care the raw areas will contract and partially epithelialize by ingrowth from surrounding skin areas and possibly also from persistent remains of skin glands. Areas that heal from skin remnants may require no further treatment because the full thickness of the derma has not been destroyed but epithelialization by ingrowth (or seeding) from surrounding skin is for a long time extremely delicate and easily destroyed and the scar upon which it rests may subsequently have to be shifted or removed to allow free movements.

Even the most severe deformities including union of the arm to the chest wall can be relieved by division and dissection that permits the fullest relaxation with complete abduction of the arm. The dissection must be carefully done to avoid injury of the deeper structures, and complete abduction must not involve ruthless rending of underlying muscles. Concurrent grafting is done with the arm held at a right angle to the chest which position is maintained until the healing is completed (Figs 2, 3, 4).

Skin consists essentially of a thick, elastic, deep layer with a thinner protective covering. Dermal normally rests upon a yielding base and epithelialized scar is a very poor substitute for normal skin and subcutaneous tissue when this scar is thick and unyielding. It is an encumbrance. When lost over a large area, normal skin is best substituted for in most cases with free grafts of split skin of a thickness greater than that of the Ollier Thiersch graft as it has usually been described. The thick split grafts should be of sufficient size to cover the whole area with one or as few pieces as possible. (Fig. 6.)

When this thick split graft is smoothly fixed to an even firm surface by suture and pressure it can fulfill the highest possibilities, but when the surface is uneven a full thickness skin graft may give a better appearance, this point, however, is

usually not of importance when the area is covered by the clothes. For a comparison of the technique and uses of the split and the full thickness graft, see references 1 and 2 (Fig. 5).

Under split grafts there is always some contraction of the base on which they are put, but there is great power in the arm and shoulder actively to resist contraction and, because of this, the split graft is well adapted for covering defects here.

In cases of long standing with the fixation over a limited area the abductor muscles may have drawn out the scar into one or more soft webs, or plicae which permit free movement. In these cases operation is done chiefly to do away with the webbing. The fold is split and each side is converted into an appropriate flap by incisions that may somewhat resemble a Z. There were 4 such patients in this series. (Fig. 8.)

In 11 of the cases axillary flaps from neighboring skin or soft scar were used in conjunction with split free skin grafts as an extra protection for the axillary vessels and nerves, but, with care, we have so far succeeded in not exposing the axillary contents during the mobilization. In the late healed cases there was usually an increase in the quantity of fat, as happens everywhere that the depth of a natural surface fossa has been lessened by the traction of overlying or neighboring scar.

Treatment of one of these cases is difficult in many ways and well planned surgery of proportionate magnitude will usually prove a saving of both time and effort. On account of the general condition the scarcity of available skin or for some other reason pinch grafts, small deep grafts, small Thiersch grafts, implantation grafts, or tunnel grafts might be advantageously used to tide over some phase of the treatment, but these are not always conservative of the donor area. Homografts might be considered with these mentioned because, at times, they apparently stimulate subsequent spontaneous epithelialization but in our own cases we have not observed the homograft itself to persist. (Figs. 1, 2, 3, 7.)

Releasing scars and allowing the defect again to contract but adds to the total amount of scar (Fig. 8).

CANNULA GASTROSTOMY AND ENTEROSTOMY¹LESTER R. DRAGSTFDT PH.D. M.D. H. E. HAYMOND M.D. AND JAMES C. ELLIS M.D. CHICAGO
From the Department of Surgery of the University of Chicago

THE production of an artificial opening through the abdominal wall into the stomach or intestine was attempted early in the history of surgery and a great deal of ingenuity has been displayed in the various operative procedures employed. These have been described so thoroughly by R. W. McNeal (1931) that no reference need be made here to this extensive literature. Attention has been directed to the development of simple methods whereby nutrient materials and fluids might be introduced directly into the stomach or intestines at will and yet prevent the escape of the highly irritating digestive secretions which produce such a troublesome excoriation of the surrounding skin. Not only has the operation of gastrostomy and enterostomy been of great service in the clinical treatment but it has been a most useful tool in the hands of the experimental physiologist in the study of digestion. It is the purpose of the present communication to describe a technique embodying the principles of one of the older experimental methods with certain modifications which has been useful to us both in the clinic and in work on lower animals and which in certain features seems to be an improvement on methods in current use.

The essential apparatus consists of a brass tube or cannula with certain accessories all heavily plated with gold throughout. Its shape is best appreciated by inspection of the accompanying photographs and drawings. The cannula with the circular flange is used for the production of a gastric fistula. The curved rectangular flange is designed for the small intestine. The introduction of the cannula is quite simple. An incision is made in the viscus (stomach or intestine) just large enough to admit the flange of the cannula. Closure is made with a running suture and two purse string sutures to invert the mucosa snugly about the shaft of the cannula. The greater omentum is now carefully wrapped about the shaft and secured in place by several sutures. This step is most important, since it seals the fistulous tract from the general abdominal cavity and thus prevents a peritonitis. It represents an adaptation of the principle utilized by London (1927) in his

Fig. 1. Photograph showing the gold plated cannulas and accessories. Dimensions of the gastrostomy cannula to the left: total length 10 centimeters, inside diameter 1.20 centimeters, diameter of circular flange 4 centimeters. Dimensions of enterostomy cannula at the right: total length 10 centimeters, inside diameter 0.80 centimeters, length of flange 3 centimeters, width of flange 1.5 centimeters.

Fig. 2. Drawing illustrating the use of the cannula for gastrostomy. Attention is directed to the layers of omentum interposed between the stomach and the anterior abdominal wall.

angiostomy experiments on lower animals. The distal end of the cannula is now brought through the abdominal wall by means of a stab wound, preferably 2 or 3 inches from the abdominal incision. To facilitate its passage through the abdominal wall and to secure a tight fistula a sharply pointed cap may be screwed to the distal end of the cannula. This is, of course, immediately replaced by the blunt cap or the rubber tube adapter for convenient syringe feeding. It is advisable to wrap a gauze strip about the protruding shaft until the stomach and omentum

have become firmly adherent to the abdominal wall. Patients experience surprisingly little inconvenience from the cannula and have no difficulty in the introduction of semi-solid food and fluids. There is no leakage, no excoriation of the surrounding skin, and hence no necessity for the constant changing of dressings.

To date we have employed this technique for the production of a gastrostomy in 6 patients suffering from carcinoma of the esophagus with stenosis. The legends accompanying the photographs give in sufficient detail the histories in these cases.

A more rigid test of the method has been secured in its use for the production of various types of gastric and pancreatic fistula in lower animals. Under these conditions a much more irritating fluid is drained away and a satisfactory adjustment of dressings cannot be obtained. Nevertheless during the past 4 years it has replaced other

methods in our laboratory, as incomparably more convenient in affording water tight fistulae for the quantitative collection of secretions and in its complete freedom from digestion of the skin of the abdominal wall. Here again the accompanying photographs best illustrate the technique employed

LEIOMYOMA OF THE JEJUNUM

CLAUDE F. DIXON, M.D., F.A.C.S. AND J. A. STEWARD, M.D., ROCHESTER, MINNESOTA

(Section on Surgery, The Mayo Clinic)

BENIGN tumors of the small intestine are sufficiently rare to deserve reporting. The series of cases from The Mayo Clinic reported by King in 1917 contained only one benign tumor of the small intestine in more than 44,000 cases in which laparotomy had been performed and Mallory in 4,165 postmortem examinations found only 11 such tumors.

The types of benign tumors found in the small intestine are polyp (adenoma), lipoma, fibroma, myxoma, myofibroma, myxofibroma, myoma,

neurofibroma, angioma, endothelioma, and teratoblastoma (5, 13, 20). The relative frequency of the different types is still in doubt. Polyps are said to be the most common (5) but the probable tendency of these tumors to disappear spontaneously (1, 2) in some cases and their definite relationship to malignancy (17, 20) make their classification somewhat uncertain. Of the other benign tumors, lipomata, myomata, and fibromata are the most common; the remainder are extremely rare. Despite the report of King that myomata occurred in his series more frequently than lipomata (45 of the former and 29 of the latter), the series of Kasemeyer in which lipomata were twice as common as either myomata or fibromata in causing intussusception, the 104 cases of lipomata reviewed by Derocque as compared with 45 cases of fibromata reviewed by Clifton and Landry, and 58 intestinal myomata reported by Hake, lead to a different conclusion. Although there are no conclusive data on the

Fig. 1. a Intussusception of jejunum b Jejunum and tumor after reduction of intussusception

Fig. 2. Leiomyoma which extended into the lumen of the jejunum.

FIG. 3. Section of leiomyoma stained by van Gieson contrast method to show smooth muscle.

subject we believe that lipomata occur with about twice the frequency of either myomata or fibromata. If myxomata are included with fibromata to which they are generically similar the incidence of fibromata and myomata is about the same, although the question is still in dispute (12). It must be remembered that in the various cases reported the tumors were examined by many pathologists using various staining methods, and if it were possible for all the specimens to be examined by the same person with uniform stains, the resulting ratios might be entirely different or might substantiate the term "fibroid" as used by Bland Sutton, or the more accurate term "leiomyoma" as used by Rieniets for the small benign tumors of the stomach.

REPORT OF TWO CASES

CASE 1. A man, aged 57 years, came to the clinic December 5, 1931. He complained chiefly of a painful mass in the abdomen. The trouble had begun in April, 1931, as an occasional knife-like pain before stool. The attacks became more frequent and for the previous two and a half months had occurred 10 to 15 minutes after eating and were accompanied by the formation of a mass. The mass in the abdomen would shift from left to right and disappear when massaged. There had been neither nausea nor indigestion, but much eructation and borborygmi.

General examination showed the abdomen to be tender at the left of the umbilicus; an indefinite mass was palpable. Operation was advised for a tumor of the small intestine.

December 10, 1931. Intussusception of the middle of the jejunum was reduced (Fig. 1) 12 centimeters of the intestine was resected and an end-to-end anastomosis was made for the removal of a tumor of the small bowel (Fig. 2). Enterostomy was made above the anastomosis. The pathologist found a leiomyoma 3.5 centimeters in diameter showing myxomatous degeneration (Fig. 3). The patient's convalescence was uneventful and he was dismissed December 31.

CASE 2. A man, aged 57 years, came to the clinic November 30, 1931, with the complaint of a sense of fullness

FIG. 4. Leiomyoma of jejunum attached to scar on abdominal wall.

in an operative scar. In December, 1930, he had been operated on and stated that he thought a ruptured appendix had been removed and the abdomen drained. The operation was followed by a stormy convalescence which confined him to bed for 7 weeks. Afterward he recuperated steadily but had gas pains at the site of the scar and could feel a lump in the wound.

General examination was negative except for the right rectus incision. In the center of the incision was a smooth, firm mass, about 9 centimeters in diameter, which was partially fixed, it was painful only when pulled outward from the abdominal wall. Excision of the mass was advised.

December 3, 1931, the scar and the mass were removed. The mass was incorporated in the musculature of the lower part of the jejunum and it was necessary to resect the muscle down to the mucosa to remove the tumor (Figs. 4 and 5). The appendix was atrophic but otherwise normal. The pathologist reported degenerating leiomyoma (Fig. 6) of the jejunum (6 by 4 by 4 cm.) attached to the abdominal wall. Convalescence was uneventful and the patient was dismissed December 2.

The etiology of intestinal fibromata (the term generally used in clinical literature for these tumors) is not known (3) and the theory of inclusion or embryonal rests (6, 14) is at present as acceptable as any other.

The position of the fibromata may be intraluminal or extraluminal, a division which Hertzau thought to be due to the tumor arising from the submucous connective tissue in the first type or from the subserosal tissue in the second type. The most thorough report on the subject is the review of 45 cases of fibroma by Clifton and Landry. In 25 of these cases the tumor was in

Fig. 5 Tumor and attached scar of abdominal wall.

the small intestine and in all but 2 cases was intraluminal in type. The average age of the patients affected was 39 years, most of them were between 30 and 60 years, although Willis reported the case of a fibroma in the intestine of a girl aged 8 years. The tumor occurs almost equally in the two sexes and is most common in the ileum.

The outstanding clinical characteristic of fibromata of the small intestine is that of causing intussusception. Bland Sutton reported a case of an extraluminal fibroma causing obstruction by torsion of the intestine, but intussusception was present in 23 of the 25 cases of fibroma of the small intestine reviewed by Clifton and Landry. That benign tumors frequently cause intussusception in adults had been previously pointed out by Elliot and Corcoran, who found them to be the cause of intussusception in 60 of a collection of 300 cases. This is in contrast to malignant lesions in the small bowel. Although malignant lesions in the small bowel are by far more common

Fig. 6 Section of tumor stained by van Gieson contrast method to show smooth muscle.

(10) the incidence of intussusception is low. Judd in reporting 24 cases of carcinoma of the small intestine observed in The Mayo Clinic prior to 1919 noted only 2 cases in which intussusception was present, and Rankin and C. W. Mayo in a report of 31 cases from The Mayo Clinic from 1919 to 1929 failed to mention intussusception as a complication. The reasons for this lack of invagination are probably the frequency of the napkin ring or circular type of carcinoma and the comparative rapidity with which adhesions are caused in malignant cases.

The means whereby the intussusception is caused has been considered by various authors, and Jason and Filiberbaum summarized the hypothesis into the following: (1) the weight of the tumor dragging the intestine; (2) violent peristalsis due to a reaction to a foreign body; (3) spasm of the intestine at the site of the tumor; (4) perverted action of muscles; and (5) paralysis of the bowel. It is probable that several of these factors enter into all cases of intussusception.

The intussusception caused by a fibroma may be acute, recurrent or chronic, and the clinical picture will vary with the type as well as the situation of the obstructing lesion. Since the majority of these lesions are situated below the middle of the jejunum, the fulminating symptoms of obstruction high in the intestine are usually absent. In the acute cases a sudden onset of cramp-like pain and a mass in the abdomen are the best guides to the diagnosis. In Elliot and Corcoran's 60 cases of intussusception caused by benign tumor a mass was palpable in 22. In the recurrent type a shifting abdominal tumor with the attacks will indicate the trouble. The chronic type, in which there is sufficient lumen to allow

the passage of some material may offer the most difficult diagnosis and be indistinguishable from chronic constipation or partial obstruction from any cause. Nausea and vomiting are variable symptoms. Melena may result from an ulceration of the mucosa covering the tumor but is not as common as in cases of intussusception among children.

Examination of the intestinal tract by the roentgen-rays must be done with great caution. In the acute type of intussusception it is manifestly contra indicated, and in the recurrent and chronic types an acute attack with complete obstruction may be precipitated.

With the diagnosis made surgical exploration is the treatment indicated. Although it is possible that benign tumors and whole intussusceptum may pass by way of the anus, delay in operating cannot be condoned. The operative procedure must be adopted to the case and to the surgeon's skill. Resection and an anastomosis is usually done. The operative mortality reported in the series of 25 cases reviewed by James and Sappington, and the 45 cases reviewed by Clifton and Landry was slightly more than 27 per cent.

SUMMARY

Two cases of fibromata of the jejunum are reported. The patients were both aged 57 years. The first case was a fibromyoma of the intraluminal type, which caused recurrent attacks of intussusception. The second case was a fibroma of the extraluminal type and was attached to an abdominal scar and caused slight symptoms on pressure.

THE ADVANTAGES OF AN EXTREME TRENDLENBURG POSITION IN OPERATIONS OF THE UPPER RESPIRATORY TRACT

JOSEPH A. PETTIT M.D. F.A.C.S. PORTLAND, OREGON

THE reason for the occurrence of pulmonary abscess and pneumonia following operative procedures has occasioned considerable discussion. Clinical evidence and experimental evidence are often conflicting especially the statistics of various operators who have written upon this subject. Some experimenters have reported failures to produce pulmonary abscess by the introduction of infected material into the bronchi unless there has been some injury to the mucous membrane lining the bronchi while others have reported a certain percentage of success. It is possible that the failure of animal experiments along this line may be due in part to the natural immunity of dogs to the infectious micro-organisms to which a human being is vulnerable.

A few writers have reported a large series of tonsillectomies with but few or no pulmonary abscesses or pneumonia following. The majority of clinicians, however, acknowledge varying percentages. It is claimed by some that pulmonary abscess following tonsillectomy is embolic in origin and does not come from aspiration. It is notable however that the greater percentage of pulmonary abscesses occur following operations in the upper respiratory tract and oral cavity and the majority have followed tonsillectomies. Lung abscess does not often follow drainage appendicitis and pelvic operations, or others remotely situ-

ated of a similar type from which the transference of septic emboli to the lungs should be expected.

The first reported cases were by Richardson about 18 years ago and up to that time the attention of the profession had not been called to this possibility. Prior to that such complications were attributed to other sources.

The frequency of the occurrence of postoperative lung abscess varies with different observers. Moore reports one in about every 2,500 tonsillectomies. Lord in reviewing 227 cases of lung abscess recorded that 66 were postoperative and of this number 82 per cent followed operations about the upper respiratory tract.

Various observers have made a series of bronchoscopic observations following tonsillectomies and have found aspirated blood in the trachea in a rather large percentage of cases. It is recognized that the respiratory tract rid itself of foreign particles with considerable facility if normal reflexes are undisturbed and if the mucosa is unbroken infection is less frequent. However aspiration of any infectious germ or pathological tissue is a factor of risk especially if the mucosa is broken or irritated by inhalation anesthesia.

It is the purpose of this paper to call attention to a technique we have always used which minimizes and probably in most cases eliminates any aspiration of blood secretions, or infective mate-

Fig. 1. Application of apparatus.

Fig. 2. Tongue depressor and hand controlled mouth sucker are used except in cleft palate cases.

the passage of some material may offer the most difficult diagnosis and be indistinguishable from chronic constipation or partial obstruction from any cause. Nausea and vomiting are variable symptoms. Melena may result from an ulceration of the mucosa covering the tumor but is not as common as in cases of intussusception among children.

Examination of the intestinal tract by the roentgen rays must be done with great caution. In the acute type of intussusception it is manifestly contra indicated, and in the recurrent and chronic types an acute attack with complete obstruction may be precipitated.

With the diagnosis made surgical exploration is the treatment indicated. Although it is possible that benign tumors and whole intussusceptum may pass by way of the anus, delay in operating cannot be condoned. The operative procedure must be adopted to the case and to the surgeon's skill. Resection and an anastomosis is usually done. The operative mortality reported in the series of 25 cases reviewed by James and Sappington and the 45 cases reviewed by Clifton and Landry was slightly more than 27 per cent.

SUMMARY

Two cases of fibromata of the jejunum are reported. The patients were both aged 57 years. The first case was a fibromyoma of the intraluminal type which caused recurrent attacks of intussusception. The second case was a fibroma of the extraluminal type and was attached to an abdominal scar and caused slight symptoms on pressure.

JEJUNAL ULCER

AN ANALYSIS OF THIRTY SIX CASES AND STUDY OF THE LITERATURE¹

EDWARD B. BENEDICT M.D., BOSTON

JEJUNAL ulcer following gastro-enterostomy is so serious a complication and its incidence is so much in dispute that a careful review of cases proved by operation or demonstrated by X ray examination should be of interest. Balfour's latest reports indicate an incidence of only 3.26 per cent, which contrasts sharply with figures of 20-34 per cent reported by Berg, Lewisohn, Strauss and others. Prominent German and Austrian surgeons have for some time been advocating radical resections for peptic ulcer because of the high incidence of jejunal ulcer. Whether there is a racial difference in the size and type of peptic ulcer encountered in different countries is an interesting question. Walters and Snell gave their attention to this question last year when traveling in Europe and concluded that owing perhaps to coarse irritating dietary habits the type of multiple ulcers with gastritis met with in the people of central Europe seems amenable only to radical surgery, whereas the usual type of single ulcer found in France, England and America responds well in 90 per cent of the cases to less radical surgical procedures. That diet alone is probably of great importance in the development of gastroduodenal ulcer is indicated by Bergsma's recent observations on the black people of Abyssinia in whom the incidence of peptic ulcer is very high and whose chief article of diet from the age of 2 years is sour bread with a sauce of 50 per cent cayenne pepper!

INCIDENCE

The number of cases of duodenal ulcer for which posterior gastro-enterostomy has been done at the Massachusetts General Hospital and in which jejunal ulcer has subsequently been proved at operation in this hospital is only 7. As there have been 732 gastro-enterostomies for duodenal ulcer in this hospital the incidence of proved jejunal ulcer is practically 1 per cent. It has not been possible, however, to trace all cases. There have been 14 cases of jejunal ulcer proved by operation in this hospital in which the gastro-enterostomy was done at another hospital. To compensate for our untraced cases these 14 may be added, making 21 cases of proved jejunal ulcer. If we still use 732 gastro-enterostomies as a basis, the incidence of jejunal ulcer is 2.9 per cent. If 15

more cases of probable jejunal ulcer, diagnosed clinically and by X ray, are added the incidence of jejunal ulcer is nearly 5 per cent. The latter figure, however, is almost certainly too high for it includes unproved cases as well as cases in which the gastro-enterostomy was performed at another hospital. Taking the incidence of 2.9 per cent as most likely to be correct, we find it in close agreement with Balfour's latest figure of 3.26 per cent.

AGE

The age incidence of course depends considerably on the age at the time of the gastro-enterostomy. The youngest patient in this series (Case 1) was only 18 years of age at the time of gastro-enterostomy and only 21 at the time of recurrence of ulcer symptoms. At the age of 24 years a secondary operation was done and jejunal ulcer demonstrated. The oldest patient (Case 3) was 56 years old at the time of gastro-enterostomy, 5 years later this patient required repair of a gastrojejunal fistula. In general jejunal ulcer occurs during the middle period of life, the average age at the time of the secondary operation being 43 in this series. According to Smyth gastro-jejunal ulcer has been reported in a baby 2 years old after gastro-enterostomy for pyloric stenosis and also in a patient of 81 years after gastro-enterostomy for ulcer.

SEX

Jejunal ulcer like gastroduodenal ulcer, is largely a disease of men, only one woman being found in this series. Balfour reported 270 cases with only 22 women. That average gastric acidity is higher in the normal male than in the normal female has been shown by many observers and confirmed recently by Lerman, Pierce, and Brogan. This may be of significance in the high proportion of males having gastroduodenal and jejunal ulcer.

ETIOLOGY

Primary jejunal ulcer. Jejunal ulcer is for all practical purposes an artificial disease secondary to gastro-enterostomy. Richardson, however, was able to collect 10 cases of primary jejunal ulcer from a complete review of the literature, adding to the report 2 cases which occurred in the Massachusetts General Hospital. The etiology

of these rare primary jejunal ulcers is not known.

Gastrojejunal ulcer. A distinction should be made in postoperative ulcer between *gastrojejunal* ulcer which occurs exactly at the line of suture and *jejunal* ulcer which occurs a few centimeters away from the stoma, usually in the efferent loop. In the former it is the generally accepted belief that the use of non-absorbable suture material plays a major rôle in the etiology. This point has been well established experimentally by Groenerud, who performed gastro-enterostomy on several hundred dogs, finding secondary gastro-jejunal ulcer common when silk sutures were used but uncommon when absorbable sutures were used. Clinical experience substantiates these observations.

Secondary jejunal ulcer. The etiology of postoperative jejunal ulcer occurring a few centimeters from the anastomosis, is not so clear. A number of theories will be discussed.

Hyperacidity theory. Hyperacidity is probably the most important factor. Acid gastric juice impinging constantly on jejunal mucosa unaccustomed to receive it might reasonably be expected to cause trauma and to predispose to ulcer formation. In support of this theory are a number of clinical and experimental observations.

1. Jejunal ulcer is almost unknown after gastro-enterostomy for carcinoma of the stomach. Key however did report a case of jejunal ulcer after partial gastrectomy and anterior gastro-enterostomy for carcinoma. The gastric acidity was not studied in this case and may have been high after resection. Judd also mentioned a case which occurred at the Mayo Clinic after resection for cancer. No cases have been found in the literature occurring after simple anterior or posterior gastro-enterostomy for carcinoma. This would seem to be of significance in view of the usual anacidity or hypoauidity in gastric cancer. It might be argued that such patients do not live long enough to develop jejunal ulcer but they may survive 6 months or more after gastro-enterostomy in which length of time it is possible to develop an anastomotic ulcer.

2. Jejunal ulcer is much more common after anterior gastro-enterostomy or after the Roux gastro-enterostomy en Y than after posterior gastro-enterostomy (Montgomery, Gossett, Moy nihan, Paterson). The explanation seems to be that in gastro-enterostomy by the anterior method a long jejunal loop is used thus making the stoma a long way from the neutralizing effect of the alkaline duodenal contents. Furthermore, when an entero-enterostomy is also performed as is usu-

ally the case in anterior gastro-enterostomy the alkaline juices are likely never to reach the site of anastomosis at all. Likewise in the gastro-enterostomy en Y there is very little possibility of neutralization in the jejunum near the stoma. In spite of the relative frequency of secondary jejunal ulceration after anterior gastro-enterostomy for ulcer we have observed above that it is never seen after gastro-enterostomy for carcinoma, where the anterior operation is so common.

3. Jejunal ulcer is very much more common after gastro-enterostomy for duodenal ulcer than after gastro-enterostomy for gastric ulcer. Bal four in a study of 139 cases of jejunal ulcer occurring in cases in which the original gastro-enterostomy had been done at the Mayo Clinic, found 130 followed gastro-enterostomy for duodenal ulcer and only 9 followed gastro-enterostomy for gastric ulcer. In 381 cases of gastric ulcer operated on at the Massachusetts General Hospital since 1908, jejunal ulcer has not been observed to follow gastro-enterostomy in any case. Many more cases of duodenal ulcer show hyperacidity than do cases of gastric ulcer as has been shown by Kalk at von Bergman's clinic and Hurst and Stewart in London hospitals. Quoting from Lindau and Wulff Hurst and Stewart's figures show hyperacidity in 61 per cent of cases of duodenal ulcer and in 32 per cent of cases of gastric ulcer and Kalk's figures indicate hyperacidity in 75 per cent of cases of duodenal ulcer and in only 29 per cent of cases of gastric ulcer.

4. Morton and Graham have reported the case of a patient who after cholecystectomy and drainage of the common bile duct died suddenly 24 days after operation of hemorrhage from a duodenal ulcer which had apparently formed as a result of stones impacted in both the common bile duct and the pancreatic duct with complete blockage of these secretions. As no ulcer was found at the time of the cholecystectomy the conclusion is that it developed as a result of the failure of the alkaline secretions to enter the duodenum and neutralize the gastric juice. Thus the neutralization of gastric acidity is shown to be of importance for the protection of duodenal as well as jejunal mucosa. Holzwieser's case cited by Hauser is very similar eight erosions and ulcers of the jejunum occurring in a woman of 58 years with an obstructed ampulla.

5. Jejunal ulcer is rare in women, there being only one case in this series and relatively few in the literature. Sherren has noted this and the lower gastric acidity in women believing that this indicated the importance of hyperacidity in jejunal ulcer formation.

6 Experimentally in dogs, Mann and Williamson and later Morton have anastomosed the jejunum directly with the stomach, shunting the duodenal secretions into the ileum—so called surgical duodenal drainage. When this is done a typical peptic ulcer invariably develops in the jejunum close to the pylorus where the acid gastric juice impinges upon it. When the alkaline duodenal secretions are restored to this area the ulcer heals.

7 Ivy and Fauley have shown by performing surgical duodenal drainage in dogs and leaving an inch or so of duodenum attached to the pyloric end of the stomach that ulcer always develops in the jejunal mucosa and not in the duodenal mucosa, although the latter is subjected to the same force of impinging gastric juice. This seems to indicate that, under the same conditions, jejunal mucosa itself is more susceptible to ulceration from the action of gastric juice than is duodenal mucosa.

8 Elman and Hartmann by continuous external drainage of the pancreatic secretion in dogs have shown that duodenal ulcers develop constantly under such conditions, indicating the importance of the pancreatic secretion in neutralizing the acidity of the gastric juice and protecting the duodenal mucosa.

9 Further evidence of the importance of the acidity of gastric juice in ulcer formation is brought forth by Lindau and Wulff, who call attention to ulcer of Meckel's diverticulum in which gastric mucosa with fundus glands can be demonstrated, and in which the presence of free hydrochloric acid has proved to be a regular finding. These authors point out that peptic ulcer is found in the esophagus, cardia, area of pyloric glands, duodenum, jejunum (postoperatively) and in Meckel's diverticulum, and that in all these areas there is activity of hydrochloric acid, which they regard as of very great importance in etiology.

10. Rivers and Wilbur have recently called attention to gastro-ileal ulcers following the unfortunate surgical error of gastro-ileostomy when gastrojejunostomy was intended. They conclude that "clinical evidence is suggestive that the potentiality for the development of peptic lesions arises whenever and wherever any segment of intestinal mucosa is exposed to the eroding action of the gastric chyme."

11. Morton found by passing duodenal tubes in 33 patients with peptic ulcer that all showed free hydrochloric acid in the duodenum, whereas 13 persons without peptic ulcer did not show free hydrochloric acid in the duodenum.

12. Goldberg has recently called attention to experimental peptic ulcer formation in dogs in which a section of ileum has been used to form a permanent external fistula from a gastric pouch. The pure gastric juice acting on the mucosa of the ileum is apparently the important factor in ulcer formation in these animals.

Theory of infectious origin Another factor which may be of significance in jejunal ulcer formation is infection. It is impossible to evaluate its importance, but it is reasonable to state that no medical treatment of peptic ulcer is complete without attention to foci of infection such as teeth, tonsils, appendix, gall bladder, prostate, and cervix to which Moynihan adds that in performing gastro-enterostomy a diseased appendix or gall bladder should be removed. In this connection I will quote Wilkie's views on peptic ulcer.

The prevalence of dental infection is to my mind the most important single factor in determining the frequency of peptic ulcer. In many of these cases we recover from the pyorrheal pockets the same streptococcus as we find in the ulcer. The combination of an ulcer in the stomach or duodenum or both with infection in both gall bladder and appendix is quite common. All these lesions must be dealt with if complete and lasting relief is to be obtained." In this connection Wilkie cites a case of jejunal ulcer with associated inflammation of the appendix and gall bladder. *Streptococcus viridans* was grown in pure culture from regional lymph glands from all three sites and when this streptococcus was injected into rabbits both duodenal ulcer and cholecystitis were produced!

Other factors in the etiology of gastrojejunal and jejunal ulcer are related (1) to *general medical management*, such as diet, smoking, use of alcohol, etc., or (2) to *faulty surgical technique*, such as the use of non absorbable sutures, too small a stomach, badly placed stomach, or (3) to *improper selection of cases*. The importance of proper medical care after gastro-enterostomy is generally recognized, though it is difficult to know for how long a period a strict diet should be followed. Many patients after a few months on a careful regimen find that they can return to normal dietary habits without ill effect. Others have to be careful to avoid highly acid fruits, meat and fried or rich foods, and of course some have to be still more careful to live on a very bland diet. Excessive use of tobacco or alcohol should be avoided though some patients tolerate them. Faulty surgical technique seems to be an obvious factor in etiology. Gastro-jejunal ulcer with small pieces of silk or linen suture material hanging from its center has been

TABLE I—SUMMARY OF PROVED JEJUNAL ULCER CASES
Jejunal Ulcer Proved at Operation

Recurrent symptoms	X-ray evidence of jejunal ulcer	Total acidity	Date of operation for jejunal ulcer	Type of operation for jejunal ulcer	Result
Posterior Gastro-Enterostomy Done at Massachusetts General Hospital					
Pain in epigastrium, melena	Shoerd con- tracted stomach	Not stated	(1) 1-9-11 (2) 11-5-11	(1) Excision, (2) P.G.E. anastomosis	(1) Not relieved. (2) Several hemorrhages from duodenal ulcer. Symptoms-free past 8 yrs. on milk diet only
Hematemesis, melena, pain to left of umbilicus	Yes	Not stated	1919	P.G.E. and entero-enterostomy anastomosis	Fairly well on medical treatment past yrs. Seen 2-9-11
Melena; diarrhea after meals; pain in epigastrium, diffuse, reaching to umbilicus	Yes gastro- jejunal ulcer detected	1 cm.	1921	Closure of gastrojejunal fistula and P.G.E. with excision of jejunal ulcer	Died 13 days after operation—peritonitis
Hematemesis, melena, pain in epigastrium, occasionally radiating to left inguinal region	Yes	1 cm.	1921	Subtotal gastrectomy. Sham- maker method	Doubtful improvement. Died 8 mos. after operation, after amputation both legs for arteriosclerotic gangrene also had tertiary syphilis and tabes
Hematemesis, melena, epigastric pain	Yes	Not stated	1926	Excision of gastrojejunal ulcer; resection of stomach. Pólya anastomosis	Feeling very well and eating almost everything. Seen 3-1-33
Antacid diarrhea, melena	Yes, gastro- jejunal ulcer detected	60 c.c.m.	1931	Duplication of P.O.E., closure of fistula	Gaining weight and doing well 3 yrs. Needs further operation 4-3
Anorexia, melena, vomiting; dull pain under right costal margin	Yes	41 c.c.m.	1932	Separation of O.E., pyloric loop. Pólya method, 2-3 of stomach removed	Patient writes that he is cured. Has pain relieved by hot milk, anorexia, vomiting, and gas 2-29-31
Posterior Gastro-Enterostomy Done at Various Hospitals					
Epigastric pain as before P.G.E., most recent abdominal pain at left, steady hematemesis; melena	Yes	7 c.c.m.	1931	Gastric resection posterior Pólya anastomosis	Relieved, gaining weight 3-16-31
Pain at umbilicus, radiating down toward pelvic catheter	Yes	0-25 O 50-4-51 38 c.c.m.	1933	P.G.E. anastomosis. Maltine diet. Pyloric resection	Feeling well 4 mos. after operation. Vomiting, hematemesis. Gastroenterostomy Feb. 1933
Vomiting; pain in L.U.Q., over most of left abdomen; "hump" in L.U.Q.; diarrhea, loss of weight and weakness	Yes, gastro- jejunal ulcer	50 c.c.m.	1937	Subtotal resection of stomach, anterior Pólya resection of transverse colon and end-to-end anastomosis	Died 1939, cause unknown
Pain similar to that before P.G.E., starting in epigastrium, spreading to loins and chest; hematemesis; melena	No	21 c.c.m.	1939	Resection of stomach gastro- jejunostomy (Pólya)	Feeling well and eating almost everything. Seen 3-1-33
Lower abdominal pain; hematemesis; melena	No X-ray taken	Not stated	{ 7-27-40 { 7-27-40	{ Resection of jejunum. { Anterior Pólya resection and entero-enterostomy	Symptoms-free on 3-meal bland diet. Seen. 3-15-33
Pain in L.U.Q. radiating to lower quadrants and back, weakness and lower epigastric pain; melena	Yes	1-4-40 18 c.c.m. 2-22-40 85 c.c.m.	1940	Resection of jejunum with ulcer anastomosis of jejunum, P.G.E.	Died 6 days after operation of general peritonitis and hemorrhage into stomach
Hematemesis, melena, epigastric pain, gas and burning after meals	Yes	25-45-14 64 c.c.m. 11 12-16 26 c.c.m.	1943	Excision of gastrojejunal ulcer	Return of symptoms 1 mos. postoperative, weakness and anorexia. 15 yrs. later? malignancy of liver
Diarrhea and vomiting; no pain	Gastrocolic fistula	90 c.c.m.	1946	Repair of colic fistula, closure of jejunal anastomosis; resection of pyloric third of stomach. Pólya anastomosis of stomach and jejunum; colostomy	Very satisfactory. Seen 3-1-33

P.G.E. Posterior gastro-enterostomy

Cases 1, 5, 15, 17 and 30 have been previously reported by Davis, Lincoln—Surg., Gynec. & Obst., 1937, IV, 304.

*The total acidity is given in c.c.m. of 0.1 normal sodium hydroxide 1 hour after last meal. In all cases prior to 1930, histamine was not used. In practically all cases for the past 5 or 6 years, histamine has been used.

TABLE I—SUMMARY OF PROVED JEJUNAL ULCER CASES—Continued
Jejunal Ulcer Proved at Operation

Recurrent symptoms	X-ray suggestive of jejunal ulcer	Total acidity	Date of operation for jejunal ulcer	Type of operation for jejunal ulcer	Result
Anterior Gastro-Enterostomy Done at Various Hospitals					
Epigastric pain nausea vomiting gas and sour eructations	No	Not stated	9 6	Separation of P.O.E. resection of jejunal lumen suture found in jejunal ulcer	Died 3 week after operation with discharging wound and pulmonary complications
Epigastric pain 2-3 hr after meals, relieved by food and soda vomiting loss of weight	Yes Stoma closed	35 cm.	9 14	Undoing of old P.O.E. excision of jejunal ulcer	Symptoms returned 3 wks. after operation re-entry 8 mos. later with operation for recurrent duodenal ulcer partial gastrectomy and P.G.E.
Pain in epigastrium radiating to whole abdomen nausea and vomiting	No report	Not stated	10 2	Suture of perforated ulcer of jejunum	Good postoperative convalescence 7-8 1/2
Pain in lower abdomen at night and 3-4 hours after meals, relieved by food and vomiting pain at umbilicus 2-5 hrs after evening meal	Yes	55 cm.	9 3	Closure of G.E. excision of gastrojejunal ulcer gastro-duodenostomy	Symptom-free 3 mos. after operation, then recurrence of epigastric pain and vomiting treated in hospital 2 days diagnosed probably recurrence of original ulcer medical treatment advised
Epigastric pain on right no definite relation to meals, relieved by soda, heat, or vomiting gas gastritis	Yes Stoma closed	30 c cm.	9 1	Closure of subacute perforation of duodenal ulcer removal of old G.E. for gastrojejunal ulcer	Feeling pretty well, but some upper abdominal pain every 2-3 weeks, relieved by soda can eat any food. Sera 1 10-31
Pain over pubes, radiating to back, later pain in upper left abdomen, non-radiating distention relieved by food diarrhea	Gastrocolic fistula	45 c cm.	9 3	Excised ulcer lysed P.O.E. suture of colon, stomach, and intestines	Discharged from hospital 6 h. 7-7-31 No further follow-up

P.G.E. Posterior gastro-enterostomy

*Cases 5 15 7 and 10 have been previously reported by Davis, Lincoln—Surg., Gynec. & Obst., 9 7 1914

†The total acidity is given in cm. of normal sodium hydroxide 1 hour after test meal. In all cases prior to 1916 histamine was not used. In practically all cases for the past 3 or 4 years, histamine has been used.

**Reported by courtesy of Dr. A. W. Allen.

any case the gastric acidity is usually lowered by gastro-enterostomy, but there seems to be no definite relationship between postoperative acidity and jejunal ulcer. The relationship of the appendix to jejunal ulcer formation is not proved but it may be significant that in most of the jejunal ulcer cases the appendix had not been removed. Eleven of the cases showed no pyloric obstruction by X ray and although we know that many gastro-enterostomies are entirely successful even in the absence of such obstruction we feel that the most successful cases are usually those with obstruction. Five cases (6 7 8 18 20) however showing obstruction by X ray examination subsequently developed jejunal ulcers. Hence it is evident that gastro-enterostomy even when performed to relieve obstruction may result in jejunal ulcer formation. Furthermore obstruction revealed by the X ray is inconclusive unless shown at repeated examinations and confirmed by the clinical picture. Unabsorbable suture material was known to have been used in this series in only 6 of the operated upon jejunal ulcer cases

(1, 5 6 8 16 20) (sometimes only for the serous layer), in 1 case (16) the linen suture was found at the operation for jejunal ulcer. It is probably a factor of importance when used for the mucosal stitch. Six patients (Cases 1 2 10 12 17 32) in this series were only 25 years of age or younger at the time of their first operation. But in addition to their youth only one of these (Case 12) had had adequate medical treatment and 3 (or all those examined) showed marked hyperacidity, so that it is impossible to say that youth is a factor in the etiology of jejunal ulcer. In general however it may be said that a youthful patient frequently has not had time for prolonged medical treatment is likely to have hyperacidity and is therefore likely to be a poor subject for gastro-enterostomy. In one case in this series (Case 3) gastro-enterostomy was performed to anticipate possible obstruction from a suspected carcinoma of the pancreas. The subsequent development of jejunal ulcer in this case emphasizes the importance of not performing gastro-enterostomy except for very definite indications. Moynihan

*The total acidity is given in cent. of 1 normal sodium hydroxide base after ten meals. In all cases prior to 1910 treatment was not given. In practically all cases for the past 5 or 6 years medication has been used.

believes that nine out of ten failures after gastro-enterostomy are the result of the operation having been performed in the absence of any organic lesion justifying it

SYMPTOMS

The symptoms of jejunal ulcer are chiefly pain, hæmatemesis and melena. The pain is frequently described as similar to that of the original ulcer but is usually somewhat lower down and to the left of the umbilicus not infrequently radiating to the left groin and sometimes generalized to the lower abdomen. This low abdominal pain may be evidence of adhesions to the colon though after a colonic fistula is established pain may not be a prominent symptom. The pain of jejunal ulcer is less likely to be controlled by soda or dietary measures than is the pain of gastric or duodenal ulcer. This may be due to the fact that the stomach empties so rapidly through the stoma that food remains in contact with the ulcer only a very short time. Hæmatemesis and melena are very constant symptoms, one or both being present in almost all our cases though no fatal hæmorrhage occurred. Perforation into the general peritoneal cavity may occur as happened in one case in this series (Case 18) after posterior gastro-enterostomy and entero-enterostomy of much more common occurrence is perforation into the colon which occurred five times in this series or an incidence of 13.9 per cent.

DIAGNOSIS

The diagnosis depends largely on the history of gastro-enterostomy with subsequent symptoms as outlined and the X-ray findings. Camp has stated recently that in the last two years a positive roentgenologic diagnosis of gastrojejunal ulcer has been confirmed by the surgeon in 90 per cent of cases, as compared with 74 per cent ten years ago. He bases the X-ray diagnosis on (1) the presence of an ulcer niche (which he believes can be seen in about 60 per cent of cases) (2) persistent deformity of the stomach, stoma or jejunum (3) the presence of a gastrojejuno-colic fistula and (4) closure of the stoma. Camp has observed jejunal ulcer as far as 15 centimeters from the anastomosis. Of 19 cases of proved gastrojejunal or jejunal ulcers in the Massachusetts General Hospital in which an X-ray examination was made the X-ray picture was suggestive in 17 cases, or 89.5 per cent. Of the 2 cases missed by the roentgenologist one (Case 16) was in 1916 when roentgen diagnosis was less accurate than it is now and the other (Case 11) was obscured by a pyloroplasty. It thus seems evident that considerable reliance may be placed on an experienced

roentgenologist in the diagnosis of gastrojejunal or jejunal ulcer

COURSE

The course of the disease is chronic with relapses and remissions. Patients may be carried along comfortably for long periods of time on careful medical management but it is doubtful if they are ever permanently cured. There are almost always periods when rest in bed is essential because of pain or hemorrhage. A study of the results of the 15 cases treated medically in this hospital indicates that some are doing fairly well on a careful medical regimen but that very few are symptom free. All have had severe enough symptoms to necessitate hospitalization and in several operation has been advised but not performed. Perforation into the colon is a serious and not infrequent complication. A gastro-jejuno-colic fistula had occurred in 5 (Cases 3, 6, 10, 15, 1) of the 7 cases in the Massachusetts General Hospital which came to operation, or an incidence of 71.4 per cent in the operated cases. Adding the cases of probable jejunal ulcer treated medically the incidence of gastro-jejuno-colic fistula is 9 per cent in this hospital. This figure is somewhat higher than that found in the literature the Mayo Clinic figure being 11.36 per cent. The diagnosis of such a fistula is usually easy for in addition to the history of gastro-enterostomy and probably of recurrent ulcer there is likely to be loss of weight and diarrhea with grossly undigested food in the stools, and the X-ray examination is almost sure to show filling of the stomach by barium enema.

TREATMENT

With the course and complications of this artificial disease thus outlined it would seem reasonable that when the diagnosis is definitely established surgery should be the treatment of choice. Each case however presents an individual problem, and in general, medical treatment should be given a fair trial and may be reasonably successful in some cases for varying periods of time. Subjective symptoms economic disability danger of hemorrhage or perforation are very strong arguments in favor of surgery. The disease is an artificial one produced by surgical interference and presenting very definite pathology. If a competent surgeon is available why should such a disease be allowed to continue uncured? Balfour says, "The treatment of gastrojejunal ulcer is surgical. Experience emphatically teaches that when the symptoms are those of recurring ulceration, when the roentgenogram is positive and when relief of symptoms cannot be promptly attained and maintained by medical treatment,

early operation is the safest and most satisfactory method of management.

The surgical treatment of jejunal ulcer. Plastic operations at the stoma have been generally abandoned as ineffective. Under this heading is included simple excision of the ulcer with or without enlargement of the stoma, a change in location of the stoma, or the substitution of an anterior for a posterior anastomosis. All the factors which pre-disposed to the formation of the original jejunal ulcer are still present and such procedures usually result in the development of a new ulcer at the stoma or in the jejunum. Three of our cases (1, 13, 14) fall into this group and in none were the results satisfactory as one required further operation 8 months later, one died 6 days after operation of peritonitis and hemorrhage and the other suffered a recurrence of symptoms 10 months after operation.

Resection of the stomach is of course a more formidable procedure but, if sufficient stomach is removed, is followed by good results in many cases. The stoma must be included in the resected portion and also a fairly large section of the stomach otherwise we have left a big stomach with the pylorus excluded as in the von Ehselsberg operation which is known to be followed by a high percentage of jejunal ulcers (C. H. Mayo, Leriche, Fohl, Montgomery, Wright, Laher and Jordan, de Takats and Mann von Haberer). A similar anatomical arrangement exists after pyloroplasty. In three pyloroplasties in this series (Cases 11, 27, 34) jejunal ulcer has developed. However, resection of a large portion of the stomach is not by any means a sure preventive of jejunal ulcer for jejunal ulcer following partial gastrectomy has occurred in 2 cases in this series (22 and 25) and has been reported by Balfour, Starlinger, von Haberer, Gosset, Leriche, Straum, and others. Resection was done in 8 of our 17 cases operated on for jejunal ulcer with good results in 5 (Cases 5, 8, 11, 12, 15) poor results in one (Case 7) and doubtful or unknown results in 2 (Cases 4 and 10). It is possible that the failure in Case 7 can be attributed to the removal of insufficient stomach. With no mortality in these 8 cases and 5 good results, subtotal gastric resection must be seriously considered in the treatment of jejunal ulcer. It is, however, a serious operation and, should it fail, further operative procedures are practically out of the question.

Fortunately there are other procedures open to us in the surgical treatment of jejunal ulcer such as undoing the anastomosis with or without some form of pyloroplasty or gastroduodenostomy.

Jejunal ulcer is clearly the result of the original operative procedure. Therefore what could be more logical than the undoing of that procedure? The objection is at once raised that if this alone is done there may be further trouble from the original duodenal ulcer. It has already been pointed out, however, that many of these cases never had adequate medical treatment in the first place and it is not at all unlikely that in such cases medical treatment after undoing the gastro-enterostomy may control the situation. Cases 1 and 2 are examples of simply undoing the anastomosis and returning the gastro-intestinal tract to its normal state. Both of these patients are getting on fairly well now on medical treatment one of them however being limited to a diet of almost nothing but milk. If however medical treatment has been given a thorough trial before the operation and there has been definite evidence of pyloric obstruction it is well in addition to undoing the anastomosis and excising the ulcer to do some type of gastroduodenostomy or pyloroplasty. There is very good authority for such procedures. Wilkie and also Cannon have stressed the fact that some form of anastomosis between the stomach and duodenum is more physiological than gastrojejunostomy. If stricture or ulceration near the pylorus persist, Richardson has suggested that resection of the anastomosis followed by gastroduodenostomy would seem to be the ideal procedure. In discussing indications for gastroduodenostomy Balfour has included failure of posterior gastro-enterostomy due to jejunal ulcer where he says the gastro-enterostomy should be undone and gastroduodenostomy performed. Judd has also subscribed to undoing the gastroenterostomy excising the jejunal ulcer and performing a plastic operation on the pylorus if it seems best. Gosset believes closure of the gastro-enterostomy alone is inadequate and should be combined with a plastic operation on the duodenum according to Judd's method which Gosset considers the best. Von Haberer according to Best, considers the Billroth No. I the operation of choice because it is the most physiologic anatomic. In a paper on jejunal ulcer Terry concludes that, in view of the very few reported cases of ulcer of the duodenum following pyloroplasty or gastroduodenostomy it would seem wise to employ these operations in suitable cases. W. J. Mayo discussing Terry's paper said they treated gastro-jejunal ulcer by cutting off the gastrojejunostomy and doing a Finney pyloroplasty. Wright has likewise concluded that when secondary ulcers have formed it is best to cut off the gastro-

enterostomy and restore the natural channel if necessary by a plastic operation. Under such circumstances he mentions the usefulness of gastroduodenostomy and the Finney operation. In discussing 3 cases of jejunal ulcer following partial gastrectomy (reported by Down) Balfour sums up the present trend toward more physiological operative procedures on the stomach as follows:

The surgical treatment of jejunal ulcer is not difficult if the operation is carried out as soon as the diagnosis is made. Since we have seen a number of cases in which jejunal ulcers have recurred after repeated gastric resections it seemed reasonable to reunite the stomach to the duodenum rather than to continue with resections similar to those done previously. I look on the procedure as having the great advantage of giving an opportunity for a normal alkali-acid balance to be maintained. When many of the leading gastric surgeons of the world thus express themselves as in favor of some form of physiologic anastomosis between the stomach and duodenum it seems surprising that such operations are not more common.

The treatment of gastrojejuno-colic fistula is surgical. As there is likely to be soiling of the peritoneum where the fistula is undone the procedure should be as simple as possible and usually consists in repairing the fistulous opening and undoing the anastomosis restoring the gastro-intestinal tract to normal. If this alone is not successful pyloroplasty gastroduodenostomy or resection may be done later. In debilitated patients, feeding by jejunostomy may be useful in preparing them for operation. Simple repair of the fistula and undoing of the anastomosis was done in 3 of our cases (3, 6, 21). 1 patient died of peritonitis 13 days after operation, the 2 others are both recent cases, but it already seems likely that one of them will require further operation because of obstructive symptoms similar to those he had before his gastro-enterostomy. It is thus evident that gastrojejuno-colic fistula is a very serious condition and as it occurs in from 10 to 15 per cent of all jejunal ulcer cases it presents a strong additional argument for early surgery in treating jejunal ulcer.

CONCLUSIONS

The incidence of jejunal ulcer proved by operation at the Massachusetts General Hospital is approximately 2.9 per cent.

Jejunal ulcer is very rare after gastro-enterostomy for gastric ulcer and probably never occurs after gastro-enterostomy for gastric cancer.

The disease is due largely to an improper selection of cases for gastro-enterostomy.

CARCINOMA OF THE TRANSVERSE COLON

THEODORE S. RAIFORD M.D. BALTIMORE, MARYLAND

From the Departments of Surgery and Surgical Pathology of the Johns Hopkins Hospital and University

THE literature upon malignancy of the large bowel is prodigious and there is probably no phase which has escaped attention at some time or other. The opportunity of observing a recent case of carcinoma in the mid transverse colon which terminated very favorably has pointed out two aspects of the condition which have perhaps not received due consideration.

It is surprising that malignant tumors of the transverse colon occur with relative infrequency. On analyzing 297 cases of carcinomata of the colon it was found that only 22 or 7.3 per cent were located between the hepatic and splenic flexures.

It is commonly thought that due to the accessibility of this region, operative removal of such tumors is facilitated and the prognosis is good. A careful analysis of this group however reveals a mortality rate higher than is customarily found for growths in other parts of the large bowel. These deaths are due to various causes: some to faulty operative technique, some to unavoidable postoperative complications, and still others to the difficulty encountered in effecting a complete removal.

The 22 cases recorded in this hospital have been reviewed from the standpoints of clinical features, surgical technique and pathology with the intent of discovering the reasons for these peculiarities.

OCCURRENCE

Table I shows the distribution of 297 tumors of the colon in its various parts. The colon is for this purpose empirically divided into five parts: the ascending colon, hepatic flexure, transverse colon, splenic flexure and descending colon (including the sigmoid). Further subdivision seems unnecessary and ambiguous. Bearing in mind that the transverse colon is approximately the same in length as either the ascending or descending portions, it is more than accidental that carcinomata occur about one fifth as frequently in the former location as in either of the latter. A satisfactory explanation for this characteristic is entirely lacking. There is nothing peculiar in the embryology, anatomy or histology which might predispose to the infrequency with which it is invaded. It must be borne in mind however that the transverse colon is functionally more active and that stasis of fecal contents is less likely to

occur. Until the relationship between stasis, irritation and tumor formation is established, however, this cannot be regarded as a responsible factor.

AGE—RACE—SEX INCIDENCE

Carcinomata of the transverse colon are similar in respect to these features to malignancies elsewhere in the large intestine. The age incidence is most commonly in the fifth decade of life, the average age of the group being 44 years. All of the tumors occurred in members of the white race. Fourteen occurred in males and 8 in females, agreeing closely with the sex distribution in all gastro-intestinal malignancies.

CLINICAL FEATURES

The symptoms of carcinoma in the transverse colon are not unlike the clinical manifestations of malignancies elsewhere in the gastro-intestinal tract. The average duration of symptoms is about 14 months. General symptoms experienced by the patient are malaise, loss of weight, secondary anemia, and abdominal pain. More specific symptoms are apparent when obstruction is present, either partial or complete. The patient then complains of eructation, digestive upsets, fullness or distention, meteorism and constipation. When ulceration has occurred, tarry stools are frequently observed.

It is interesting that the symptoms are frequently referable to upper intra-abdominal pathology. In one instance the symptoms were characteristic of an acute cholecystitis. In several cases the symptoms and signs were mistaken for those of gastric malignancy and in none of these was the correct diagnosis made before the abdomen was opened.

The physical signs may be negligible in the early stage of the disease and nothing more than a moderate distention observed. Tumors in this region, however, are usually palpable early and by careful palpation, even a small mass can be picked up against the prominence of the vertebral column. The patients are usually underweight, pale, and undernourished. Laboratory examination reveals a moderate secondary anemia. The stools in many instances are grossly black or bloody and, in the majority, occult blood can be demonstrated. Achlorhydria is commonly associated with carcinomata of the stomach. It is surprising

however to find an absence of free hydrochloric acid in a large percentage of carcinomata of the transverse colon.

Diagnosis is usually made by the X ray films following a barium enema. These when positive on repeated examination should be conclusive but it is never amiss to perform a gastro-intestinal series as embarrassing mistakes have been known to occur following the omission of this procedure.

PATHOLOGY

The majority of tumors in this location assume the annular constricting form sometimes aptly described as napkin ring carcinoma. The early growth may appear as a small ulcer on the mucosal surface of the gut wall. The edges are hard and elevated leaving a crater like erosion in the center. The wall is thickened and indurated. As growth progresses the ulcerated area extends around the bowel more rapidly than longitudinal, leading eventually to an annular growth. When this has occurred the tumor continues to grow both longitudinally and inwardly forming a hard encircling band which constricts the lumen until in late cases it is almost entirely occluded.

Extension to the mesentery may take place. Involvement of the mesentery glands is not rare and does not seem to be dependent upon the age of the tumor. Metastases have been observed in very early cases of short duration. The liver is particularly susceptible to metastases and contained secondary growths in 27 per cent of the cases of this series. Extension to adjacent organs occurs and it is not at all uncommon to find on laparotomy a large conglomerate mass of tumor the origin of which is not determined until the specimen is dissected. Extension is particularly apt to involve the stomach in fact this had occurred in 32 per cent of the cases more than had metastasized to either the liver or lymph glands. This brings about complications both in diagnosis and treatment. The symptoms and X ray findings are frequently those of gastric pathology and the correct diagnosis is not usually made before operation. Surgical treatment is

more difficult since a partial gastrectomy is necessary to remove all possibly involved tissue. This extension may travel through the lymphatics of the omentum by which means a surprising number of omental implants occur. More commonly the growth involves the posterior wall of the stomach with which it is partly in contact. Table II shows the location of the metastases and secondary growths.

The microscopic pathology is not distinctive. The majority are adenocarcinomata. It is surprising that a large percentage of cases showed mucoid degeneration in the presence of the adenocarcinoma and were originally diagnosed colloid carcinoma. Such was the case in 60 per cent of the tumors, a much higher percentage than has been encountered in the other portions of the colon. The medullary and scirrhous types of carcinoma may also occur but are far less frequent than adenocarcinoma.

TREATMENT

The treatment of carcinoma of the transverse as well as other parts of the colon should consist of early radical excision. Since this is the most easily accessible portion of the colon the average operator regards the prognosis as good and has a tendency to exercise less care in resection. The results of surgical extirpation in 18 treated cases were not gratifying. Six died as a result of the operation 2 of peritonitis and 4 of pneumonia embolism or shock. Two died of recurrence 3 are well 5 years or more 3 are living without signs of recurrence less than 5 years after operation and 4 were improved following operation but no report as to ultimate result was obtained. Four were thought to be inoperable and eventually died of extension and metastases. Fecal fistulae developed in 4 cases. In all of these catgut was used in suturing the blind ends. It is the experience of several operators that heavy silk is safer than catgut at this site. Table III shows the results of treatment in this group of cases.

The anatomy of the transverse colon should be reviewed briefly before further approaching the

TABLE III—RESULTS OF TREATMENT

surgical treatment. Its general direction is transversely across the abdominal cavity with a variable degree of ventral and caudal convexity. It is supported by the transverse mesocolon the continuation of which forms the inferior leaf of the greater omentum. This is directly overlying the colon and in approximation to it. Near the hepatic flexure it is not entirely covered by peritoneum but overlies the right kidney and duodenum. Near the splenic flexure the mesentery is longer and allows more mobility. The splenic flexure is higher and more posterior than the hepatic. The blood supply is furnished largely by the middle colic artery arising from the superior mesenteric. It arches to the right, supplying the hepatic flexure and ramifies in the region of the splenic flexure with the left colic. The course of the middle colic is variable, but it usually curves upward about 6 to 8 centimeters to the right of the midline.

Bearing in mind these anatomical features, the mode of surgical procedure must be approached. Two methods of removal are open to the operator: local resection and resection of the entire right half of the colon with an ileocolic anastomosis.

When the tumor is located in the middle or left half of the transverse colon, local resection may be practised with impunity inasmuch as the intestine can be mobilized and anastomosis facilitated. A common mistake of resection is the removal of too much bowel, leaving short stumps upon which considerable tension must be exerted to obtain approximation. Some pathologists claim to have found evidence of malignant change in the intestinal wall, 2 inches or more from the site of the primary growth. No doubt this may be true in advanced cases but in early operable cases this statement is open to question. It is the author's impression that the removal of a wide margin of normal gut is frequently overrated. A second and perhaps more important technicality lies in the preservation of the blood supply. Meticulous care should be exercised in choosing

the point of resection so that viability of both stumps is preserved. This necessitates careful dissection of each branch of the middle colic artery which in some instances is especially difficult due to an excess of fat in the mesentery. Therefore three factors must be considered in choosing the point of resection, the blood supply, the mobility of the bowel, and the proximity to the tumor.

Two methods of anastomosis are available: the end-to-end and the lateral. The end-to-end method may be used in some cases with success, but in general is not as satisfactory as the lateral method. It requires more exacting surgical technique and the chance of leakage following anastomosis is greater. The operator may be governed by circumstance and if it is impossible to overlap the bowel without undue tension, the end-to-end method must be used. The anastomosis devised by Parker and Kerr is frequently used and is more satisfactory than the older open method.

Whenever possible the lateral anastomosis is preferable. A larger stoma is formed and there is less chance of obstruction. There are two satisfactory methods of performing this union. The first is the isoperistaltic anastomosis and is in general satisfactory except for two features. Blind pouches are left, necessitating obliteration by suture to the opposing lumen. In spite of this precaution damming up of fecal contents sometimes occurs which may cause either perforation or occlusion of the stoma. The anastomosis is dropped back into the peritoneal cavity after the operation. Should gangrene or perforation occur peritonitis is likely to result. Bloodgood devised a method to overcome this feature in 1906. He performed an antiperistaltic lateral anastomosis, but brought the blind ends out through the peritoneum when closing the wound. This method extraperitonealizes the weak blind ends and in the event of gangrene or rupture, infection takes place outside the peritoneal cavity. Thereafter nothing more harmful than a fecal fistula results which can be closed at a later date.

If the tumor is located in the proximal half of the transverse colon, the entire right half of the colon may be removed. The description of this technique can be found in all treatises on operative surgery and need not be repeated here. It involves freeing the cecum and ascending colon from the peritoneal attachments and resection of the right half of the colon together with a portion of the terminal ileum. The raw surface left is then peritonealized and a lateral anastomosis performed between the terminal ileum and the distal

transverse colon. In the hands of competent operators this is a relatively safe procedure and the operative mortality is surprisingly low. It is a longer operation and consequently attended by greater shock. The removal of such a large portion of gut results in a moderate physiological disturbance of the bowel which may not become readjusted until some months after the operation. Nevertheless it is considered an excellent operative procedure both from the standpoint of radical removal of possibly involved glands and a functionally good anastomosis.

The use of midium and deep X ray therapy has been found no more efficacious in carcinomata of the transverse colon than in other portions of the bowel, for the reason that adenocarcinomata are not radiosensitive. While it is true that irradiation may sometimes give temporary relief in late inoperable cases it rarely brings about any lasting improvement. A short circuiting operation is more desirable for the relief of obstruction.

The prognosis of carcinomata of the transverse colon should be comparable to that of carcinomata elsewhere in the gastro-intestinal tract with observation of the above mentioned technical factors. The tendency toward invasion of the stomach jeopardizes the operability but emphasizes the need for thorough examination including a gastro-intestinal series and barium enema whenever there are symptoms of intra-abdominal pathology. Far too frequently is the complete X ray examination omitted either through negligence or the desire of the physician to spare the patient discomfort in the examination or a seemingly unnecessary expenditure.

CASE REPORTS

Detailed case reports all too often confuse the reader and lend ambiguity to a surgical paper. It is the author's intention to avoid this so far as possible, but with a relatively small number of cases there are certain illustrative features which can be brought out only by a brief case history. In the subsequent reports, only those features which are of direct importance in the diagnosis and treatment of the cases are included.

CASE 1. Path. No. 45348. White female, aged 55 years. The patient had complained of headaches, constipation, and weakness for 3 years. She had felt a subjective obstruction to the bowels for 3 months and had lost 18 pounds in weight during the illness. Physical examination revealed a palpable, tender mass just above and to the right of the umbilicus. The patient was markedly anemic. An irregularity was seen in the middle of the transverse colon with the fluoroscope and in the X-ray plates. Pre-operative diagnosis: carcinoma of the transverse colon.

Operation was performed September 5, 1937. Six inches of the intestine were removed with a V-shaped piece of

mesentery for a hard constricting tumor located in the middle of the transverse colon. The mesentery contained several enlarged lymph glands. The ends of the intestine were anastomosed laterally by the "thumb" method of Bloodgood. Pathological diagnosis: adenocarcinoma, grade II with mucoid degeneration. The glands were negative for metastases. One of the blind ends broke down on the tenth day after operation with the subsequent formation of a fecal fistula. This drained persistently for several weeks but was finally closed and the patient was discharged 3 months after operation. She is well at the present time, 8 months after operation.

This patient fortunately recognized the subjective signs of obstruction before the tumor became inoperable thereby enhancing the chances of recovery. The advantages of the thumb anastomosis devised by Bloodgood are illustrated by the rupture of the blind end of bowel with a subsequent fistula. Had this occurred within the abdominal cavity a generalized peritonitis would have developed with a probable fatal termination. The condition of this patient became critical during the operation the blood pressure falling and the pulse rising. The operator, having a donor previously matched for blood transfusion, administered 500 cubic centimeters of citrated blood to the patient on the table, with the result that she left the table in excellent condition and suffered little postoperative shock. This measure if practised more frequently would no doubt avert many postoperative deaths from shock after severe operations.

CASE 2. Path. No. 44223. White female aged 56 years. The patient had suffered abdominal pain, nausea, and vomiting for 3 months and was conscious of an abdominal mass for 3 months. She had lost a moderate amount of weight. Physical examination revealed a tender palpable mass in the midline below the umbilicus. It was the size of a grapefruit with a discharging sinus. The X ray examination showed in the mid transverse colon complete obstruction to the barium enema. Pre-operative diagnosis: carcinoma of the mid-transverse colon.

Operation was done December 8, 1928. A large tumor mass was found within the sac of a ventral hernia. It was resected and the hernial defect repaired. The tumor was not attached and no enlarged glands were found. Pathological diagnosis: adenocarcinoma, grade IV, with fistulous communication to the bowel. Patient died 14 days after operation from infection of the abdominal wall and pulmonary embolism.

It is unusual that a tumor giving rise to symptoms for only 3 months could have attained this size. The patient was either unaware of pre-monitory symptoms or the tumor grew with extreme rapidity. The coincidence of a ventral hernia with the tumor no doubt confused the patient, for having the previous condition for a number of years she in all probability attributed her symptoms to it.

CASE 3. Path. No. 38244. White male, aged 35 years. The patient had suffered moderate gastro-intestinal dis-

orders for 3 months and had lost 35 pounds. He had been conscious of an abdominal mass for 3 months. The last 3 weeks of his illness were characterized by a mucous diarrhoea of foul character. Secondary anemia and cachexia were marked. A firm, tender movable mass the size of a lemon was felt below the umbilicus. Pre-operative diagnosis: carcinoma of the transverse colon.

Operation was done December 8, 1933. An annular, necrotic tumor was found in the colon extending to and involving the stomach, omentum, and mesentery. The tumor was resected together with a portion of the mesentery, omentum, and stomach wall. The bowel was joined by an end-to-end anastomosis and the stomach defect was closed. Pathological diagnosis: adenocarcinoma, grades II and III, arising in the left transverse colon. Patient died 9 hours after operation from postoperative shock.

The failure of the first physician consulted to suspect the malignancy emphasizes the tremendous importance of thorough gastro-intestinal studies in all cases of obscure disorders. This calls for an extreme nicety of judgment in deciding what examinations must be made and when, since it is obvious that every case of indigestion should not only be subjected to the routine examination, not only on account of the discomfort to the patient, but for economic reasons as well.

CASE 4. Path. N. 37357. White female, aged 60 years. This patient suffered from intermittent cramp-like pains for several months during which a small movable lump would sometimes be seen. Blood was seen in the stools on several occasions, and the patient had three transient attacks of jaundice. Physical examination disclosed a movable, non-tender mass about 7 by 12 centimeters in size, palpable in the upper right quadrant. There was an absence of free hydrochloric acid. A roentgenographic filling defect could be seen in the transverse colon. Pre-operative diagnosis: carcinoma of the transverse colon.

Operation was done May 18, 1934. A small tumor was found in the transverse colon which was freely movable. It was removed together with a portion of the transverse colon and a portion of the mesentery. The ends were anastomosed by the Parker-Kerr method. Pathological diagnosis: polypoid adenocarcinoma, grade II, with mucoid degeneration, no glandular metastases. Transient symptoms of obstruction appeared on the fifteenth day after operation, but soon disappeared. The patient was discharged well 3 weeks after operation. No ultimate result note was obtained.

The jaundice in this case could be caused by either the extension of the tumor to the periductal lymph nodes or a coincident and irrelevant condition. The obstruction after operation was probably due to a temporary volvulus or kink of the intestine. But its spontaneous disappearance rendered the complication of little significance.

CASE 5. The patient suffered weakness, anorexia, and hematuria, which led to the diagnosis of pyelonephritis and a subsequent nephrectomy which was done 4 months before present admission to the hospital. He improved slightly following this operation but suffered an exacerbation of the symptoms later with a pronounced cachexia and loss of weight. Physical examination dis-

closed a moderate distention of the abdomen with a rigidity of the abdominal muscles. Several indefinite masses were palpated in the upper abdomen. There was a hyperchlorhydria and a secondary anemia. Roentgenograms showed a defect in the greater curvature of the stomach and a spastic condition of the right transverse colon. Pre-operative diagnosis: carcinoma of the stomach.

Operation was done December 8, 1934. An exploratory laparotomy revealed an inoperable carcinoma of the distal transverse colon with metastases to the liver. Pathological diagnosis: carcinoma of the transverse colon, pressing on the stomach; no specimen removed. The patient recovered from the immediate effects of the operation but died a few months later from the extension of the disease.

The presence of a kidney lesion no doubt obscured the tumor symptoms in this case. Had there been no other pathology, the gastro-intestinal condition would have been diagnosed sooner and the tumor approached while in its operable state. The hyperchlorhydria is unusual since many cancers of the large bowel are characterized by an achlorhydria. This case illustrates the frequent confusion noted in diagnosing carcinomata of the transverse colon. The roentgenographic examination indicated a lesion of the stomach but this was apparently caused by a tumor mass in the colon producing a secondary irregularity while the absence of the typical constricting tumor in the colon left it free from roentgenographic defects.

CASE 6. Path. No. 35793. White male, aged 46 years. Intermittent lower abdominal pain had been noticed for 3 years. Exploratory laparotomy 1 year before admission revealed multiple tumors in the bowel. Following this the patient was temporarily improved but had a subsequent recurrence of symptoms with increased severity, hiccoughs, dysuria, and loss of weight. Clinical examination revealed visible peristaltic waves and meteorism. A crater shaped ulcer was found in the rectum. A secondary anemia was present and there was a roentgenographic defect in the transverse colon. Pre-operative diagnosis: carcinoma of the mid-transverse colon.

Operation was done August 4, 1934. The entire right colon was resected for a large mass arising in the mid-transverse colon and adherent to the stomach, gall bladder and omentum. Several isolated polyps were found in the removed bowel. A lateral ileocolostomy was then performed. Pathological diagnosis: adenocarcinoma, grade III, mid-transverse colon; multiple benign polyps. A fecal fistula formed in the scar which refused to heal and the patient was discharged unimproved at his own request and no subsequent note has been available.

The multiple polyposis was apparently regarded by the first operator as a benign condition, and no attempt was made at operative removal. The treatment of choice would have consisted of removal of all the involved bowel, since carcinomatosis is a frequent coincident condition. Multiple carcinomata are rare and furnish the main argument in favor of malignant change in previously existing benign polyps.

CASE 7. Path. No. 35606. White male, aged 38 years. The patient had suffered weakness, loss of weight and anorexia for 7 months with dull epigastric pain increasing in severity and frequency for 3 months. Nausea and vomiting, melena and diarrhea were present for 1 month. Physical examination disclosed a moderate abdominal rigidity, gastric achlorhydria, and secondary anemia. A fatuous communication between the stomach and transverse colon was visible in the X-ray plate following a barium enema. This arose at the site of a filling defect in the colon. Pre-operative diagnosis: carcinoma of the transverse colon.

Operation was done March 31, 1923. A portion of the transverse colon and a section of the stomach wall were resected for a large friable polypoid growth arising from the colon and extending to the stomach. The continuity of the colon was re-established by lateral anastomosis and the defect in the stomach closed. Pathological diagnosis: adenocarcinoma, grade II with mucoid degeneration. Glands were negative for metastases. The patient died 7 days after operation from generalized peritonitis.

When a cancer has advanced to the stage illustrated by this case the outlook is extremely poor. The operation is long and difficult and even with the most perfect technique is hazardous. This is another of the cases in which the tumor grew rapidly and involved the stomach but in which in addition a fecal fistula had formed.

CASE 8. Path. No. 35633. White male, aged 63 years. Alternating constipation and diarrhea had annoyed the patient for 3 years. During this time he had sometimes been conscious of an abdominal mass. He suffered frequent attacks of colic like pain, which were often relieved coincident with a squirting sensation. He had lost considerable weight. A hard tender movable mass the size of an orange was noticed below the umbilicus. Free hydrochloric acid in the gastric contents was not noted. A roentgenographic defect was visible in the first third of the transverse colon. Pre-operative diagnosis: malignancy of large bowel.

Operation was done August 7, 1923. A large mass arising in the transverse colon extending to the stomach and adherent to the omentum and small intestine was removed by resecting a portion of the transverse colon and a piece of the stomach wall. After separating the mass from the other involved structures, a lateral anastomosis of the colon was performed and the defect in the stomach closed. Pathological diagnosis: adenocarcinoma, grade III with mucoid degeneration. The patient died 14 days after operation from pneumonia.

The patient's own description of his condition is oftentimes invaluable. For instance this patient stated that he felt a 'squirting' sensation which relieved pain and distention. Obviously this could be caused by nothing other than partial obstruction of the bowel allowing only small amounts of fecal material to pass at a time. Of similar value is the patient's description of a taste of hard boiled eggs following eructation and regurgitation. The flat taste of acid free stomach contents is immediately suggestive of achlorhydria. One patient complained that his clothes fitted too tightly so that he was not able to wear his belt comfortably but at the same time he

was losing weight. These features pointed to a moderate, almost imperceptible distention but persistent and sufficient to acquaint the patient with an unnatural condition in his abdomen.

CASE 9. Path. No. 35217. White female, aged 45 years. The patient had suffered vague attacks of indigestion marked by cramping pains and bloating sensation for 1 year. At the most recent attack 1 week before admission, she vomited food material ingested 3 days previously. She had lost 15 pounds in weight. A moderate fullness of the abdomen was evident and roentgenographic filling defect was present in the left transverse colon. Pre-operative diagnosis: carcinoma of the large bowel.

Operation was done June 9, 1923. At exploratory laparotomy an inoperable carcinoma was found arising in the left transverse colon involving the stomach and adherent to the parietal wall. A palliative colocolostomy was performed. Pathological diagnosis: carcinoma of the transverse colon, no glandular metastases. The patient died in 3 months' time from an extension of the disease.

It is unfortunate that often the symptoms brought about by these cancers are so mild that the patient is not alarmed before the disease has advanced to an inoperable stage. An excision could have been attempted but since so few cases involving the stomach wall recover, the operator displayed good judgment in doing nothing more than a palliative operation thereby giving the patient freedom from symptoms during the remaining months of her life.

CASE 10. Path. No. 57807. White female, aged 70 years. This patient complained of constipation for 10 months, during which time she was frequently nauseated and sometimes vomited fecal material. Gastro-intestinal series 5 months before admission was negative. Physical examination disclosed a superficial resistance in the upper left quadrant overlying a definitely outlined mass, which was irregular in shape, fixed and tender. There was a roentgenographic obstruction just proximal to the splenic flexure. Pre-operative diagnosis: carcinoma of the transverse colon.

Operation was done October 5, 1922. At exploratory laparotomy an inoperable tumor was found arising from the transverse colon, adherent to the jejunum and stomach. It was the size of an orange, was nodular and hard, and metastatic nodules were found in the omentum and liver. Pathological diagnosis: carcinoma of the transverse colon, no specimen was obtained. The patient died 5 months after operation from extension of the disease.

Spasticity of the colon not infrequently produces an obstruction which can be mistaken for an organic lesion by the X-ray findings alone. Therefore, it is important not only to repeat the gastro-intestinal series but to observe the patient fluoroscopically as well.

CASE 11. Path. No. 50673. White male, aged 45 years. The patient suffered from intermittent pain in the left lower quadrant and a marked diarrhea for 8 months following an operation for acute intestinal obstruction. He was sometimes conscious of a mass in the left side during an attack. Physical examination revealed the abdomen tympanitic

and tender to palpation on the left side. A roentgenographic defect was present near the splenic flexure in the transverse colon. Pre-operative diagnosis: partial obstruction due to peritoneal adhesions.

Operation was done June 15, 1922. A tumor the size of a lemon was found in the left transverse colon attached to the stomach. It was freed and resected together with adequate normal bowel and a lateral anastomosis performed. Pathological diagnosis: adenocarcinoma, grade I, with mucoid degeneration; no glandular metastases were found. The patient was discharged well 3 weeks after the operation.

It is remarkable that although symptoms had been present before the first operation, no tumor was found. Evidently it must have been present at that time and was overlooked at exploration. Fortunately for the patient it was of low grade malignancy and in spite of delayed removal a good result was achieved. Too much emphasis cannot be laid on the necessity of a thorough exploration at every laparotomy.

CASE 12. Path. No. 83466. White male, aged 60 years. Three years before admission a local physician had found in the abdomen a mass which had increased very little in size. Pain, jaundice, vomiting, and cachexia had been present 1 year. At physical examination an indefinite, slightly tender mass was felt in the upper right quadrant. Roentgenograms showed an abnormal position of the intestines in this region due to an extra lumbar mass. Secondary anemia was marked and occult blood was found in the stools. Pre-operative diagnosis: malignancy of the large bowel.

Operation was done July 9, 1921. A tumor the size of an orange in the right transverse colon, was resected with a piece of mesentery containing several large glands. The bowel was anastomosed by the end-to-end method. Pathological diagnosis: adenocarcinoma, grade I, with mucoid degeneration; glands negative for metastases. Patient was well 10 years after operation.

It is difficult to understand why the first physician consulted allowed this patient to continue without hospitalization for 3 years following the first appearance of the mass. It is perhaps another case in which the patient is alarmed by symptoms of discomfort rather than the presence of an abnormal mass. A gratifying result following the removal of a mass of this duration is unusual and was no doubt due to its extremely low grade of malignancy.

CASE 13. Path. No. 88670. White male, aged 53 years. For 6 weeks this patient had suffered intermittent cramp-like pains and meteorism. Malabsorption and anorexia accompanied these symptoms. At physical examination indefinite peristaltic waves and a definite bulging mass at the umbilicus were visible. This mass was firm, nodular and freely movable but not painful. Pre-operative diagnosis: carcinoma of the large bowel.

Operation was done February 25, 1922. A tumor was found in the mid portion of the transverse colon. This was resected with 3 inches of normal bowel on either side and a V-shaped piece of mesentery including several enlarged glands. A lateral anastomosis was performed between the

blind ends. Pathological diagnosis: adenocarcinoma, grade II, with mucoid degeneration; the glands showed no metastases. The patient was well 8 months after operation, but no further information was obtained.

This patient's symptoms were not severe. The neuroathenic patient usually causes the physician no end of trouble by his magnification of minimal symptoms but it is to be said in their favor that few neuroathenics die of cancer. This patient in spite of his mild symptoms sought the advice of his physician early. If every patient recognized the possible significance of premonitory symptoms the death rate from cancer would be considerably lower.

CASE 14. Path. No. 84976. White male, aged 54 years. Pain in the left side had been present intermittently for 7 months, and the patient was conscious of an abdominal mass for 4 months, before admission. The stools were frequently black and tarry. Occult blood in the stools comprised the only positive finding on physical examination. X-ray examination was negative but an exploratory laparotomy was deemed expedient. Pre-operative diagnosis: deferred.

Operation was done November 5, 1916. A small, annular carcinoma was found in the transverse colon. It was resected and the bowel ends joined by lateral anastomosis. Pathological diagnosis: adenocarcinoma, grade II, with mucoid degeneration. The patient remained well for a year, then returned with numerous metastases to the liver and stomach from which he died a few months later.

It has been said by eminent surgeons that one of the justifications of laparotomy is to establish a diagnosis. This brings about many unnecessary operations but in a few cases such as Case 14, has made possible the diagnosis of a lesion of great significance. There was little in the clinical history to indicate a carcinoma. One should be suspicious, however, when pain of a dull aching character is more or less constant over a number of months. It is unusual for malignancy to recur in the bowel as late as 4 years, and naturally one suspects the presence of a new tumor but since no autopsy was performed this point remained unsettled.

CASE 15. Path. No. 89763. White male, aged 41 years. A subjectively noticeable mass had been present in the right side for 6 weeks, causing moderate pain, dull and aching in character. In the upper right quadrant a hard nodular tender mass could be felt. Roentgenograms showed an obstruction in the first third of the transverse colon. Pre-operative diagnosis: malignancy of large bowel.

Operation was done January 30, 1918. The entire right half of the colon was resected together with the terminal ileum for a large mass arising from the transverse colon and involving the duodenum and ascending colon. Pathological diagnosis: medullary carcinoma without metastases. The patient was discharged from the hospital well but no ultimate result note was obtained.

Resection of the first half of the colon is sometimes a beneficial procedure. In this case the

tumor had involved the ascending colon and it was thought expedient to remove as much bowel as possible. The operation involves little more technical difficulty than simple resection and frequently gives a much better result.

CASE 16. Path. No. 18672. White male, aged 47 years. For 3 months the patient had suffered from cramp-like pains in the abdomen and a sensation of fullness. He had been moderately constipated and vomited twice. Gaseous eructation and regurgitation which was at first acid in taste, changed to a fecal character. He had lost 15 pounds. Peristaltic waves were seen in the upper abdomen, most prominent on the left side, where there was a superficial resistance to the abdominal wall. A gastro-intestinal series of roentgenograms indicated a pyloric obstruction with 24 hour retention. Pre-operative diagnosis: carcinoma of the pylorus.

Operation was done December 24, 1915. When the abdomen was opened the operator found a huge mass in the region of the gall bladder arising from the transverse colon and involving the stomach and gall bladder to such an extent that removal was out of the question. A palliative gastro-enterostomy was performed. Pathological diagnosis: carcinoma of the transverse colon. No specimen was obtained. The patient was discharged in 18 days improved, but died 4 months later with extension of the disease.

This patient showed symptoms of upper abdominal pathology which justified the diagnosis of carcinoma of the stomach. The presence of gall stones confused the picture but in spite of this a lesion in the lower tract was indicated by the characteristic fecal vomiting.

CASE 17. Path. No. 17777. White female aged 60 years. The patient had suffered intermittent attacks of pain and vomiting which were partially relieved by emetics for 6 months. The attacks increased in frequency and severity. She had lost some weight. The abdomen was found to be moderately distended and just to the left of the umbilicus was felt an indefinite slightly tender mass. Pre-operative diagnosis: malignancy of the bowel.

Operation was done May 20, 1914. On exploration a hard, annular tumor was found in the transverse colon. It was resected with the customary V-shaped piece of mesentery after ligation of the main branches of the colic vessels. The blind ends were anastomosed by the method of Bloodgood. Pathological diagnosis: adenocarcinoma grade III, encircling the lumen and producing partial obstruction. One of the blind ends broke down 8 days after operation with a resulting fecal fistula. This closed itself 5 weeks after operation. The patient was well when last heard from 5 years after operation.

Very few patients seek medical advice for constipation. It is nevertheless one of the most valuable and constant symptoms of gastro-intestinal tumors. Many individuals are constipated but very few over 40 years of age have a sudden and constant change of bowel habit without an underlying cause. This case illustrated again the advantages of 'Bloodgood's thumb anastomosis.'

CASE 18. Path. No. 14518. White female, aged 64 years. This patient had suffered from occasional attacks

of cramp-like pain for 3 months. She had lost 18 pounds in weight. When examined on entrance to the hospital the patient was evidently suffering from an acute obstruction. She was vomiting and in acute pain. The abdomen was extended and tympanitic. Pre-operative diagnosis: acute intestinal obstruction.

Operation was done July 21, 1913. A colostomy was immediately performed to relieve the obstruction. At exploratory laparotomy 10 days later a small growth was found at the junction of the first and middle thirds of the transverse colon causing a complete obstruction. The tumor was mobilized and removed after the method of Mikulicz, in two stages. Pathological diagnosis: adenocarcinoma grade IV surrounding the bowel and producing almost complete obstruction. The patient returned to the hospital 5 years later with a recurrence of the tumor in the psoas muscles. She died shortly after the second admission.

Carcinoma of the transverse colon do not customarily produce complete obstruction. When this occurs the underlying condition is apt to be overlooked and recognized only at operation. Two stages of operation are necessary in most cases, the preliminary colostomy for relief of obstruction preparatory to removal at the second. On the other hand certain operators feel that the patient suffers less from one operation and therefore remove the tumor when the abdomen is first opened.

CASE 19. Path. No. 12784. White male aged 42 years. The patient had definite attacks of obstruction lasting 1 or 2 days at a time for a period of 2 weeks, increasing in severity and frequency. Six days before admission he became conscious of a mass in the middle of the abdomen. Constipation was marked and he suffered discomfort following the ingestion of solid food. He had lost an indefinite amount of weight. Examination disclosed a definite hard, immovable mass on the left side of the iliac fossa. Other examinations were negative. Pre-operative diagnosis: malignancy of the bowel.

Operation was done May 15, 1912. The operator found on opening the abdomen a small annular tumor in the distal third of the transverse colon with enlarged glands in the mesentery. The tumor was resected and the ends of the bowel anastomosed by the lateral method. Pathological diagnosis: scirrhous carcinoma surrounding and constricting the intestine. Metastases present in the enlarged gland. The patient died 14 days after operation from bronchopneumonia.

The scirrhous type of tumor, that is to say the epithelial tumor characterized by a heavy fibrous reaction is most frequently responsible for constriction. This type of tumor is difficult to demonstrate by palpation but causes its symptoms early and metastasizes late. It is therefore, one of the most favorable types to treat. The death from pneumonia in this case was not the fault of technique, and the autopsy showed a cleanly healed anastomosis.

CASE 20. Path. No. 12331. White male, aged 58 years. This patient suffered attacks of dyspepsia for a number of years. Three weeks preceding his admission to the hospital he had an acute exacerbation characterized by eructation and copious vomiting. Examination disclosed a

bulging mass in the right iliac fossa which was tense and at times showed peristaltic waves. This was tympanitic on percussion. A ray examination revealed a dilated cecum with obstruction at the first third of the transverse colon. Pre-operative diagnosis: malignancy of the transverse colon.

Operation was done January 1, 1918. On opening the abdomen the operator found the cecum tremendously dilated, the result of an obstructing tumor mass in the transverse colon. He removed the right half of the colon *in situ* and performed an ileocolic anastomosis. Pathological diagnosis: adenocarcinoma, grade II with mucoid degeneration. The patient died 8 days after the operation from generalized peritonitis.

When markedly distended the wall of the cecum is thinned to such an extent that an anastomosis is hazardous in view of the possible leakage. In Case 20 this fact led the operator to remove the entire right colon. In spite of this precaution, however, the patient died of generalized peritonitis.

CASE 21. The patient had suffered increasingly severe attacks of pain in the right abdomen for 6 months. She had lost 25 pounds in weight 2 weeks preceding admission. The history she had expected a mass in the lower iliac fossa. She admitted to an acute obstruction. The patient entered the hospital in agony. The abdomen was distended tympanitic and extremely tender. Pre-operative diagnosis: acute intestinal obstruction.

Operation was done August 5, 1920. The operator performed a laparotomy rather than a preliminary hysterectomy. He found in the left half of the colon a mass which had completely encircled the lumen causing almost complete obstruction. The tumor was resected in an adequate margin of normal bowel and a Y-shaped piece of mesentery containing a few enlarged glands. The bowel ends were anastomosed with the end-to-end method. Pathological diagnosis: adenocarcinoma, grade II of the obstructing "napkin ring" type; the glands were negative for carcinoma. The patient suffered partial obstruction following the operation for 2 years. At a second operation adhesions were released which had caused a partial obstruction of the site of the anastomosis. The patient is well at present 4 years after the first operation.

In this case the operator felt justified in doing the excision at the first operation. The fact that the patient did not recover entirely does not discredit the method of procedure.

CASE 22. Path. N. C-5074. White female aged 66 years. This patient had noticed an upper abdominal mass for 3 years. For 2 years previous to admission she had been annoyed by a persistent diarrhea. The mass had steadily increased in size but was not painful. She had lost 15 pounds in weight. Examination revealed a mass in the upper midline the size of an orange, which seemed to be adherent to the transverse colon and omentum. Pre-operative diagnosis: carcinoma of the transverse colon.

Operation was done June 3, 1928. On opening the abdomen the operator found a mass 3 centimeters in diameter surrounding the transverse colon in its middle portion but producing very little obstruction. This mass was resected with a few centimeters of normal bowel on each side and a section of the mesentery. The ends of the bowel were anastomosed by the end-to-end method. A portion of the

ileum adherent to the tumor was also resected. Pathological diagnosis: adenocarcinoma grade IV, transverse colon. The patient was discharged well and to date 4 years later has had no sign of recurrence.

This case again represents the type of patient who allows an abnormal mass to go unnoticed for 5 years and consults a doctor only when symptoms occur which interfere with his daily activity. Modern medical teaching advocates early consultation for suspicious symptoms. The education of the laity leaves much to be desired and until patients learn to seek medical advice not only for annoying symptoms but also for any abnormal growth or condition, the ability of the physician to help them is lessened.

SUMMARY

Carcinomata are relatively rare in the transverse colon, only 7.3 per cent of all carcinomata of the colon being located in this region.

The clinical features differ little if any from those of carcinomata elsewhere in the bowel. Symptoms frequently simulate those of upper abdominal pathological conditions, such as gastric lesions or gall-bladder disease and confusion of diagnosis is not rare. An achlorhydria is found in the majority of cases. Diagnosis is made by X-rays following both a barium meal and a barium enema. In cases in which the findings are doubtful the series should be repeated.

It is surprising to find that tumors arising from the transverse colon involve the glandular system relatively infrequently. Metastases have a predilection for the liver. More common than metastases, however, is direct extension to the stomach and omentum, thereby causing the condition to be confused with carcinoma of the stomach. The majority of these tumors assume an annular constricting form and cause symptoms of partial obstruction.

Histologically most of the tumors are of the adenocarcinoma type with secondary mucoid degeneration. This accounts for their tendency toward extension to adjacent structures with increased operative difficulty.

The optimum treatment consists of early radical resection followed by anastomosis. The operator should give particular attention to the amount of bowel resected, the preservation of blood supply to the stumps, the prevention of tension on the anastomosis, and the method of anastomosis. Lateral anastomosis is to be preferred to the end-to-end method. The isoperistaltic or thumb method of anastomosis devised by Bloodgood is an advantageous procedure when sufficient bowel can be obtained without tension. This method

allows a possible rupture of the blind ends to take place outside the peritoneal cavity without causing peritonitis.

The results of treatment in 22 cases have not been gratifying. Five year cures have resulted in only 3 cases and cures of shorter duration in the same number. Postoperative deaths were 6 and

deaths from inoperability or recurrence numbered 6.

The evaluation of early symptoms by the clinician with a resultant early diagnosis and careful attention to the above mentioned technical factors by the surgeon should enhance the patient's chances of recovery.

PUNCH BIOPSY IN TUMOR DIAGNOSIS

WILLIAM J. HOFFMAN, M.D., NEW YORK

Clinical Fellow in Cancer Research, Memorial Hospital

IN a previous communication¹ the author described a new technique and instrument for obtaining biopsy specimens and reported the results obtained with it in the diagnosis of twenty tumors. Since the publication of that paper the design of the instrument has been improved and an additional series of cases has been accumulated. This paper will describe the new punch, its advantages, technique of its use, methods of preparing the material obtained, and the results attained in the biopsy of 100 tumors.

The new punch consists essentially of three parts:

1. A tubular sheath fitted by a set screw to a forceps-type handle bearing a yoke which provides longitudinal movement to a specimen cutter operating within the sheath.

2. A specimen cutter, the lance pointed tip of which serves as a trocar when the instrument is held in the closed position.

3. An insulated electrode the diameter and length of which are such that it may be introduced through the sheath and project beyond its end.

The sheath (Fig. 1) is a hollow metal cannula 12 centimeters long and 3 millimeters in diameter. Its distal end is ground to a circular cutting edge; its proximal end terminates in a tapered ferrule which is fitted to the handle by means of a set screw. The ferrule will accommodate the tip of a Luer syringe.

The specimen cutter (Fig. 1) is a cylindrical rod 15 centimeters long and 2.5 millimeters in diameter, fitting snugly within the sheath. Its proximal end terminates in a knurled knob and immediately distal to the knob is transfixied by a cross pin which engages in the yoke of the movable handle.

By this means the specimen cutter can be extruded from or withdrawn into the sheath. The distal end of the cutter is ground to a sharp, lance point, and when the handles are closed, projects beyond the sheath to form a trocar. Immediately proximal to the lance point the shaft is cut away so as to form a hook 5 millimeters long, the sharp edges of which fit snugly against the edge of the sheath when the cutter is withdrawn into it, thus exerting a shearing action on anything caught between the jaws of the cutter and the sharpened edge of the sheath. The forceps type handle consists of two limbs provided with finger holes and so pivoted that approximation or separation of the handles causes retraction or extrusion of the specimen cutter.

The electrode (Fig. 1) is a slender conductor 18 centimeters long and 2 millimeters in diameter, capable of being introduced through the interior of the sheath and of being extended about 15 centimeters beyond its edge. It is insulated over its whole surface except at its distal extremity where it terminates in a hemispherical knob 2 millimeters in diameter. The proximal end is fitted with a standard insulated split connector designed to receive the connecting cable tip of a source of coagulating (surgical diathermy) current.

TECHNIQUE OF PUNCH BIOPSY

The skin and tissues overlying the suspected tumor are infiltrated with novocain and some of the anesthetic is injected deeply along the proposed path of the instrument, puncture of the tumor being avoided however. A 3 millimeter stab wound is then made through the skin with a sharp pointed bistoury. With the punch closed so that the cutter is withdrawn into the sheath, only the sharp lance point being left exposed, the instrument is introduced through the puncture

Fig. 1. The three parts of the biopsy punch. Insulated electrode, specimen cutter, sheath fitted to forceps-type handle.

wound and thrust through the subcutaneous tissue into the tumor. When the point is felt within the tumor at the site selected for biopsy, pressure is made on the knob of the specimen cutter and the handles allowed to open. This causes the exposure of the hook shaped cutter. Gentle outward traction causes the hook to imbed itself into the tumor. The handles are then closed, thus causing the cutter to be withdrawn into the sheath and cleanly cutting away the tissue caught between the cutter and the sheath. The cutter is then completely withdrawn with its contained specimen through the inside of the sheath without contaminating the intervening normal tissues, leaving the sheath in position. If additional tissue is desired, the cutter is reintroduced and as much tissue as may be required is removed through the same puncture without an additional breach being made in the tumor. The insulated electrode, connected to a source of coagulating current, is then introduced through the sheath so that the tip of the electrode occupies the point on the tumor from which the specimen was cut away. A current of about 250 milliamperes is switched on, the electrode is held in contact with the area for about 2 seconds, and then slowly withdrawn with

Fig. 3. Specimen is withdrawn through the sheath without contaminating the normal intervening tissues, leaving the sheath in place.

Fig. 2. The punch introduced through puncture wound and the cutter extruded into the tumor ready to cut specimen.

the punch so that a thin film of coagulation is produced along the needle track.

Biopsy of cyst wall. If, when the punch is introduced, there is a sudden loss of resistance and the suspicion verified that the tumor is a cyst, the cutter is extruded within the cyst cavity and then drawn outward slightly so that the hook is imbedded into the proximal wall. Closure of the handles causes the cutter to punch out a portion of the cyst wall, and the specimen thus obtained may be drawn out through the sheath in the usual way. The cyst contents may be allowed to drain out through the sheath. If the fluid is too viscous to flow readily, the handle of the punch should be disconnected so as to permit the attachment of a syringe to the proximal end of the sheath and the aspiration of the contained material. If desired, opaque media may be introduced through the sheath for radiographic determination of the relations of the cyst to the surrounding structures.

Biopsy of prostate gland. Biopsy of the prostate gland is performed in a manner similar to that already described for other localities. The punch is introduced through the perineum at a point about 1 centimeter lateral to the midline and the point of the punch is thrust forward into the selected area of the prostate, being guided by a palpating finger in the rectum.

Fig. 4. The electrode has been introduced through the sheath and is shown coagulating the opening in the tumor and the needle track.

Fig. 5 Case 82. E. L. Punch biopsy of breast tumor. Paraffin section. Infiltrating duct carcinoma.

Preparation of the specimen The piece of tissue obtained by the punch measures 5 by 5 by 2.5 millimeters and is large enough for an immediate smear frozen section or paraffin preparation. If the tissue is soft and cellular a smear may be made by crushing a small portion between two glass slides or by touching the specimen to several areas on a glass slide previously warmed over a flame. This will cause the specimen to adhere and thus detach some cells. These smears when stained by hematoxylin and eosin afford a finished preparation in 6 to 8 minutes.

The solid piece of tissue is placed in 10 per cent formalin and carried through the regular stages of fixation to be made into permanent paraffin block preparations. Four or five sections are usually cut from these blocks and mounted on a single slide. The finished result is a section of an actual piece of undistorted tissue from which a pathological diagnosis can usually be made. If greater haste is required, a quick paraffin section can be prepared in about 3 hours.

In this series of 100 tumors the biopsy specimens, as a general rule, were prepared as immediate smears and paraffin sections. The advantage of the former is that a diagnosis may possibly be made in a few minutes; the disadvantage is that because the characteristic structure is lost the diagnosis of a smear must rest on the abnormal morphology of some clumps of cells. The information gained is, therefore, often limited. The paraffin sections require longer to prepare but afford an excellent final result which, except for size, is similar to the sections ordinarily encountered by pathologists. Because they present a section of undistorted tissue their diagnosis does not demand the special experience required in the interpretation of smears. It naturally follows

Fig. 6 Case 100. E. B. Punch biopsy of tumor of scapula. Paraffin section. Large spindle and giant cell osteogenic sarcoma.

also that more information can be gained from the section than from the smear. For instance, one can determine not only whether or not a certain tumor is malignant, but often also its pathological classification and whether or not it is likely to prove radiosensitive.

CLINICAL APPLICATIONS

The biopsy punch has been employed at the Memorial Hospital in the diagnosis of tumors located within the body beneath normal overlying structures. It has not been used within the abdominal or thoracic cavity and only with caution in the neighborhood of important vessels and nerves. By this means it has been possible

- 1 To diagnose obscure tumors entirely lacking pathognomonic features which would have indicated their character.

- 2 To obtain definite knowledge of the pathological type of a disputed tumor and thus decide

Fig. 7
of thin.
malign

upon the treatment (whether surgery, irradiation, or both)

3. To secure adequate histological proof of the nature of inoperable tumors destined to be treated by irradiation

4. To determine the ultimate effect of irradiation on tumors apparently successfully treated by that method several years previously

CLINICAL RESULTS

In a series of 100 punch biopsies done during the past 2 years at Memorial Hospital, there have been no accidents. Hemorrhage or infection have never occurred. Trauma is negligible since only a single puncture is made. The danger of local or general dissemination is probably slight; the coagulation of the puncture wound in the tumor and of the needle track attempts to eliminate this danger.

This series of 100 punch biopsies included tumors of breast, prostate, bone, cervical, axillary and inguinal nodes as well as subsurface tumors generally. The consistence and structure ranged from that of a simple cyst to that of an osteogenic sarcoma of bone. In every case tissue was obtained on the first attempt at biopsy. From the specimens obtained from these 100 tumors, 93 positive diagnoses were made (93 per cent). In 7 instances the material obtained by the punch failed to reveal any evidence of neoplastic disease although there was evidence in 4 of these cases to warrant that clinical diagnosis. In the 3 remaining cases (33, 35 and 37) there was no palpable tumor present and the only evidence of abnormality was an increased consistence of the breast. These cases are here listed as failures although it is doubtful that any malignant tumor is present. Thirty-six of these 100 tumors have been removed surgically and the whole specimens submitted to pathological study. In 34 of these cases the diagnosis made after examination of the whole specimen agreed with that made from the specimen obtained with the punch. The 2 exceptions were Cases 9 and 32. In both these instances the punch had not been introduced into the tumor and only normal tissue had been obtained. In no case on the other hand, has a positive diagnosis of malignancy made from the biopsy punch material been contradicted by the diagnosis made after examination of the whole excised tumor.

Seventeen of these tumors had been treated by heavy doses of interstitial irradiation from 1 to 7 years previous to punch biopsy, so that they were reduced to hard, shrunken, and, in some instances, calcified nodules of scar tissue. In 12 instances, strands of carcinoma cells were demonstrated

among the dense whorls of radiation fibrosis. In the 5 remaining cases, no cancer cells could be demonstrated. In these latter 5 cases the cancer presumably has been destroyed. In each, the persistent tumor was reduced to a small nodule and there was no clinical evidence of activity. They are therefore listed among the successful biopsies since it is a fairly reasonable assumption that the cancer has been eradicated.

ADVANTAGES

Among the advantages of this instrument and technique are these:

1. By means of this instrument and technique of biopsy, early diagnosis may be obtained at a time when pathognomonic clinical features are not yet developed.

2. It is a minor procedure done under local anesthesia in the physician's office at the time of the first examination. Most patients who refuse the suggestion of an operative biopsy consent readily to a punch biopsy.

3. A solid piece of unchanged tissue is obtained.

4. The piece of tissue is large enough to exhibit the characteristic structure of the portion of the tumor from which it was removed, and to furnish material for immediate smear, frozen section or paraffin preparation.

5. The tumor is punctured but once although additional pieces of tissue may be obtained through the original puncture wound, if desired.

6. The cutting action is positive; the tissue is cleanly cut away; the specimen is not crushed or coagulated. The normal structural relations, in most instances, are preserved.

7. It is successful in a wide variety of material, whether fluid, semi-fluid, caseous, soft cellular, densely fibrous or osteoid in character (bone tumors which have eroded the cortex).

8. By means of the punch a specimen may easily be obtained from the wall of a cyst and by means of a syringe fitted to the sheath its contents may be evacuated or opaque media injected.

9. The opening in the tumor and the needle track are coagulated before withdrawal of the punch, thus rendering less likely the dissemination of the disease.

10. The punch in 100 cases has never failed to obtain a specimen from any tissue into which it has been introduced. Successful diagnoses were made from material obtained in 93 percent of cases.

SUMMARY

A new technique and biopsy punch are described and illustrated. By means of this punch

and technique an actual undistorted piece of a suspected tumor is obtained through a small puncture wound and removed through a sheath without contaminating the intervening normal tissues. The opening in the tumor and the needle track are coagulated by an insulated electrode connected to a source of high frequency (surgical diathermy) current as the instrument is withdrawn.

The use of the punch and the methods of preparing the specimen are described. Biopsies by this method have been performed on 100 patients at the Memorial Hospital, this group including a wide variety of tumors and many of dense fibrous structure.

An actual piece of tissue was obtained in each case on the first attempt. From these specimens paraffin sections and smears were prepared. Successful diagnoses were made in 93 instances (93 per cent). Thirty-six of these tumors were later removed surgically and the punch biopsy diagnoses were checked by comparison with the patho-

logical diagnosis made after examination of the whole specimen. In all but 2 cases the final pathological diagnosis agreed with the diagnosis made from the punch biopsy specimen. The exceptions were cases in which the punch had not been introduced into the tumor and only normal tissue had been obtained. The accuracy of diagnosis in these checked cases was thus about 94 per cent.

The action of the instrument is safe, simple, and positive. In the whole series there has not been an instance of fungation, infection, or hemorrhage. The danger of local or general dissemination appears to be slight; trauma is negligible; the coagulation of the puncture wound in the tumor and of the needle track is an attempt to eliminate this danger.

This article was awarded Certificate of Honor, Class II by the American Medical Association at the Philadelphia Session, June, 1931.

The author gratefully acknowledges the co-operation of M. Reinhold W. Ryder of the American Cystoscope Makers, Inc., whose technical knowledge and mechanical skill were of material assistance in developing this instrument.

GASTRIC ULCER IN ITS RELATION TO CARCINOMA OF THE STOMACH

NO more illuminating study of cancer of the stomach has been published in recent years than the paper by Alvarez dealing with 41 physicians who were treated for it at the Mayo Clinic. Physicians are supposedly aware of the devious ways of this treacherous disease, are supposedly on the alert for its recognition, are supposedly convinced that in the battle against it surgical treatment and prompt surgical treatment is the only hope of salvation. But what did this group of physicians do? Did they promptly suspect cancer when they developed symptoms of gastric discomfort, of prolonged and progressive digestive disturbance, of actual obstruction? Did they promptly submit to radiological study? Did they promptly demand surgical exploration? The great majority of them did none of these things. The great majority of these men and women who should have known better either ignored their symptoms entirely or else permitted themselves to be treated for indefinite periods of time by medical measures apparently without

suspecting that they had set their feet on the way that leads inexorably to death. Small wonder in the face of this record that laymen procrastinate as they do when the shepherd strays: one cannot expect the sheep not to wander from the path.

Particularly noteworthy in this study, just as he is noteworthy in any similar study, is one special type of patient. He tells a long story of previous indigestion which has perhaps responded well in the past to medical treatment but which now remains obdurate to it. Or he suddenly exhibits an exacerbation of symptoms or a change in symptoms. That was the sort of history that was given by 21 of the 41 patients Alvarez studied, and it is the sort of history that immediately introduces either the possibility of a previous ulcer or the absolute certainty of one. The relation of gastric ulcer to gastric carcinoma is a question upon which authorities of equal eminence hold opinions that are diametrically opposite, but Alvarez is perfectly correct when he says that the man who can ignore such facts as these has a mind that is impervious to evidence of any kind.

The origin of cancer is an academic consideration, as is the question of the exact percentage of gastric ulcers which turn into cancer or the number of cases of cancer which are superimposed upon ulcers. The microscopic, radiological, and clinical criteria which must be invoked to solve the problem fade into insignificance beside the fact that some cancers apparently develop from ulcers, that some ulcers apparently develop into cancers, and that some supposed ulcers are undoubtedly cancers from their inception. The crux of the

problem therefore is whether or not the prolonged medical treatment of gastric ulcers is safe. Such treatment as Alvarez points out is always based upon the fallacious assumption that the differentiation of gastric ulceration from gastric malignancy is possible by clinical and radiological methods whereas repeated studies have shown that this is not only not possible but also that it is not even approximately accurate.

A guess which in some 25 or 30 per cent of all cases is the best that the most experienced clinician and radiologist can offer is a poor peg as Lord Moynihan says upon which to hang a man's life. And make no mistake it is a life that is in the balance. The medical treatment of gastric ulcer may be relatively safe even if it does not relieve the patient but the medical treatment of gastric cancer is equivalent to manslaughter or suicide from which ever point of view you happen to be regarding it. Gastric ulcer and gastric malignancy must be distinguished positively not probably before the medical treatment of the supposed ulcer is undertaken. The surgeon must be absolutely certain that he is dealing with an ulcer before he withholds surgery regardless of how unlikely or how uncommon he personally feels the transition to malignancy to be.

The only safe rule is to regard as cancer any indigestion, with or without other symptoms which appears after middle life in a previously well person, to regard as cancer any acute digestive disturbances in this period which are superimposed upon chronic digestive disturbances and which do not respond promptly to routine measures, to regard as cancer or as highly suspicious of it vague general symptoms even though associated gastric disturbances are lacking to continue to regard as cancer any of these clinical syndromes until it is proved beyond a shadow of doubt that

it is not cancer and to resort without delay to exploratory laparotomy if the diagnosis can not be made otherwise. The suspicion that cancer exists is the one thing that matters in malignant disease the certainty of diagnosis is frequently also the certainty of death. 'The salvation of human life says Lord Moynihan is a greater thing than the establishment of a convincing, irrefutable clinical diagnosis' and Arthur Curtis remarks in another connection that 'it is better to have a less accurate diagnosis and a more favorable prognosis. Operation on suspicion is justified in this disease in which one can scarcely tell what a day will bring forth or at what moment an operable lesion may become an inoperable one. Accurate diagnosis is a desideratum but in the absence of incontrovertible negative findings or in the presence of doubtful positive findings the surgeon is entirely justified in exploring without hesitation every person in middle life or before middle life who exhibits a dyspepsia which does not respond promptly and permanently to established methods of treatment. Cancerous indigestion has no hallmarks while it is still amenable to cure to distinguish it from indigestion of other origins. A properly performed exploratory incision was never responsible for a fatality and the multitudes cannot be counted whom it has saved from death.' URBAN MAES.

THE TRAINING OF THE SURGICAL NURSE

THE prime objective of the nursing profession as well as that of the medical profession and hospitals is the prevention and cure of disease. The duty of the hospital to train nurses is secondary to their obligation to give the best care to sick patients. The time was when the best interests of surgically sick patients were most efficiently guarded by having every pupil nurse receive

some practical training in operating room procedure, including the very particular and technical work of 'handling instruments' at operations. This covered the period of anti septic surgery and the early days of aseptic surgery when the facilities of the modern hospital had not yet been made accessible to all communities by the modern road and ambulance. In those days, fortunately past any nurse might have been called upon to prepare for a major operation in any home. Today there is rarely a call for such service. The passing of this need has not seen the nurse training schools alive to the change.

The nursing schools are putting each pupil through the mill of operating room service when today the best interests of the patient can be advanced very materially if the patient be not made the means of practice and training. No medical school trains its students in technical surgery. These students receive their technical surgical training in graduate courses as internes and as assistants to trained surgeons. The surgical clinic of today that is not associated with a training school or the one that uses graduate operating room nurses, all other things being equal is giving the best service to the patient and enabling the doctor to do his best by his patient.

The qualifications of a good surgical nurse assistant are exact, rigid and specific. A few of these are physical and nervous stability, evenness of temper, control of emotions, ability to think and to act quickly in an emergency, unusual capacity for the details and minutiae of preparation for an operation, dependability which is the result of uniformity of procedure and yet an adaptability to the infinite variations that make each similar operation different from every other one. She must have that peculiar quality of intuition that permits the *rare* assistant to be just a step ahead of the operator to anticipate his needs

before they are expressed. In a class of sixty girls, evenly selected girls, not over 10 per cent show any large proportion of these qualifications. Technical work requires specialization.

The Class A hospital of today backed by the American College of Surgeons and the American Medical Association is demanding the highest qualifications of those surgeons permitted the privilege of utilizing its operating rooms. Such a hospital states that it owes a duty to the public at large and so must insure the public that only an efficiently trained surgeon may use its facilities. This being true the same hospital should be allowed to furnish equally efficient technically trained nurses. This these very excellent hospitals do not do for the rules governing trained registered nurses, require that every nurse no matter what her personal characteristics be put through a six, eight or ten weeks operating room course and made to "assist" with at least twenty five operations. The medical college does not try to make every student a surgeon. They know that the surgeon must be born as well as made. The surgeon selects his specialty because of a love for surgery. The December 1932 examinations for nurse registration in Ohio specifically asked "For how many operations have you been the sterile nurse? Majors? Minors? The most perfectly adapted nurse for this technical work cannot hope by any stretch of the imagination to acquire proficiency in the time allotted. For a large proportion it represents time lost and lost at the expense of the hospital, the doctor, the nurse teacher and above all the patient.

How can this situation be corrected? Just two adjustments are necessary. First, change the regulations to make it unnecessary for the pupil nurse to 'handle instruments for operations. Second require that the "sterile" nurse

who "handles" the instruments at the operation be a graduate nurse. She may have an undergraduate 'sterile' assistant.

What will be accomplished by these changes? Many nurses will not be given a responsibility for which they are unfitted. Numberless hours of futile effort will be saved on the part of nurse supervisors and doctors. The placing of the student as "sterile" assistant to the 'sterile' graduate operating nurse will give the intelligent pupil all she needs of knowledge of surgical asepsis and technique and permit her to obtain this training at an early period in the school schedule to the benefit of her subsequent training. (Many advanced thinkers on the subject of nurse training feel the operating room experience should come early in the three years course.) Valuable time will be saved during each operation and while a few minutes more or less do not appreciably change the result of the average operation, these minutes saved may

mean a life saved in the bad risk and emergency case. It means the assurance of a more perfect technique to the end that complications may be eliminated. It means the surgeon's attention can be centered on the actual operation technique so that he will not have to divert his attention from the field of operation to direct a "green" nurse assistant. It means less wear and tear on the surgeon which in turn means better service to the patient.

Team work has become essential to good surgical work. The anesthetist, assistant nurses, and surgeon must work together. One new "cog wheel" in the engine or one 'green' horse in the team slows up the work and makes it less efficient. Who suffers? The patient. It therefore behooves the medical profession, hospitals, and the nurses themselves to see that the rules regulating these affairs are arranged to give the patient the best service possible. DUDLEY W. PALMER

MEMOIRS

GEORGE DAVID STEWART

DECEMBER 28 1862—MARCH 9, 1933

Thou Power Supreme, whose mighty scheme
These woes of mine fulfill,
Here firm, I rest —(they must be best
Because they are Thy will.
Robert Burns.

THE officers regents and administrators of the American College of Surgeons mourn the loss of a distinguished founder and a past president George David Stewart

He was a great man a great American a great surgeon and one of the most beloved members of the profession. Among his outstanding qualities were his strong character his human heart his love for his fellow man his unflinching friendship and loyalty his honesty of thought, his fearlessness, his tireless energy his fund of humor and his overpowering personality.

We shall miss his inspiring presence at the meetings of the College and of the Clinical Congress, his happy companionship and his courageous support of those principles which were on the side of right.

On several occasions I heard from his lips the following words from Havelock Ellis: "The present is in every age merely the point at which the past and future meet. There is never a moment when the new dawn is not somewhere breaking over the earth and never a moment when the sunset ceases to die: we should greet the new dawn serenely not hastening toward it with undue speed nor yet leaving without regret the dying light that was once dawn."

His belief that "civilization must move our profession must move both are dynamic, not static and change is life" was best exemplified by his interest in the younger men of the profession to whom his very life was a constant inspiration and in whose accomplishments lay his greatest pride. It is only fitting therefore to append some notes on phases of Doctor Stewart's life by one of his "boys" who was associated with him for twenty five years.

FRANKLIN H. MARTIN M.D.

To David Stewart

GEORGE DAVID STEWART was born in Upper Malagash, Cumberland County Nova Scotia, on the shores of Northumberland Straits, where the climate is ten months of winter and two months of late fall, a lovely place with magnificent views in the summer—when there is a summer.

The teachers in the country school which he attended were not educated, but one, who influenced his life in his tenderest years, knew how to sing Methodist hymns and how to read and write. His early education was fatuous and depended largely on the library of his grandfather—a library which consisted of the Bible Bunyan's *Pilgrim's Progress* Jeremy Taylor's *Holy Living and Dying* Boston's *Fourfold State* Baxter's *Call to the Unconverted* and *Saints Everlasting Rest* and the poems and songs of Robert Burns. The Bible he was compelled to read Robert Burns he read from choice. Hence he had a fine collection of the latter's poems tucked away in his brain for ready reference.

At the age of fourteen he ran away to sea. The schooner on which he shipped was a slow one and sailed steadily for six weeks. This sufficed to prove that seafaring was not his metier. Then by luck, on his return home a very good teacher came along and one year's instruction under that teacher enabled him to teach himself. He taught a country school later graduated from the Normal School Truro and St. Francis Xavier College Antigonish Nova Scotia and served as the principal of a village high school. He just escaped being a preacher.

Doctor Stewart graduated from Bellevue Hospital Medical College in 1889. After his internship of one year at Bellevue Hospital he was appointed preceptor in demonstrative anatomy and later professor of anatomy. It was his good fortune to serve at Bellevue under Joseph D. Bryant, Frederic S. Dennis and the elder Thayer. In 1914 he succeeded Dr. Bryant as professor of surgery, University and Bellevue Hospital Medical College, and it was here that he accomplished his greatest work. His teaching clinic was unexcelled.

As a lecturer he had few equals. At the conclusion of each lecture he insisted that the notes should be destroyed. In this way, by constant re-preparation he kept his mind virile. In recognition of his achievements his friend the late George F. Baker gave a million dollars to found the George David Stewart Endowment for Surgery.

He disliked writing articles on surgery. To use his words "There is more loose motion in the contributions to medical science particularly surgery than in anything else except in a wooden doll or a marionette."

To estimate Doctor Stewart from his published literary contributions to surgery would be unfair and unjust. His impress on American surgery can be properly evaluated only by those who have enjoyed his care and his skill, and those thousands of young men who have felt the influence of his personality and of his character as a teacher and as a man.

ARTHUR M. WRIGHT M.D.

EARLY AMERICAN MEDICAL SCHOOLS

THE EARLY HISTORY OF THE FIRST MEDICAL SCHOOL IN THE COLONIES—THE UNIVERSITY OF PENNSYLVANIA

I S RAYDEN B.S. M.D. PHILADELPHIA

WHEN William Penn founded his colony in Pennsylvania in 1682 he undoubtedly considered the medical needs of the colony for he brought with him on the *Welcome* Thomas Wynne Griffith Owen and other men trained for the medical profession arrived during the autumn and winter of the same year. In 1711 John Kearsley arrived and in 1717 Thomas Graeme. These men and others who came during that period acted as the teachers of their art and as the preceptors of the rising generation. Their successors were for the most part natives of this country. Of these, Thomas Cadwallader William Shippen Sr. Thomas Bond Phineas Bond John Redman, John Kearsley Jr. Lloyd Zachary Cadwallader Evans and John Bard played important parts in the early medical activities of the colony.

The older men fired the imagination of their apprentices with the advantages to be obtained by subsequent training at Edinburgh London, Paris, or Leyden, and most of the younger men added to their preparation by studying at one of these places.

In the settling of new countries, the first care of the planters must be to provide and secure the necessities of life. Agriculture and mechanical arts, were of the most importance the culture of the minds by the finer arts and sciences, was necessarily postponed to times of more wealth and leisure. Thus it was that on the 24th of August, 1749 Benjamin Franklin announced the prospectus of his scheme for the higher education of the youth of the colony and from it developed the University of later years.

Two years later Thomas Bond sought Franklin's assistance in the building of a general hospital for the sick and injured. On the 23rd of January 1751 "Sundry Inhabitants of the Province of Pennsylvania had petitioned the Assembly for the establishment of a permanent, public hospital. While Franklin and Bond were busy arranging for the beginning of the Academy

to train the mind, they also found time to plan the institution which was to provide the means for the founding of the Pennsylvania Hospital. The hospital was first located in a house on Market Street near Sixth, but on the 28th of May 1755 the corner stone of what is now known as the East Wing was laid on the present site. Franklin's inscription on the corner stone was as follows:

IN THE YEAR OF CHRIST
MCCCLV
GEORGE THE SECOND HAPPILY REIGNING
(FOR HE BOUGHT THE HAPPINESS OF HIS PEOPLE)
PHILADELPHIA FLOURISHING
(FOR ITS INHABITANTS WERE FORTUNE FAVORED)
THIS BUILDING
BY THE BOUNTY OF THE GOVERNMENT
AND OF MANY PRIVATE PERSONS
WAS DEVOTELY FOUNDED
FOR THE RELIEF OF THE SICK AND MIERABLE.
MAY THE GOD OF MERCIES
BLESS THE UNDERTAKING.

It was thus that the Pennsylvania Hospital and University were born of the same parentage and most of the professors in the earlier years of the Medical School were on the staff of the Hospital.

Thomas Cadwallader who had studied anatomy in London under the celebrated Cheselden, settled in Philadelphia and gave demonstrations to the physicians of the locality. Since Cadwallader established himself in Philadelphia before 1751 he was probably the first to give anatomical lectures in America. There was as yet no School of Medicine and sixteen years were to elapse before the College and Academy could boast of one.

John Morgan who had pursued his medical studies under John Redman, went to Europe in 1760. For two years he attended the lectures at the University of Edinburgh, from which institution he received his degree in 1763. Before going to Edinburgh he had attended William Hunter's lectures in London, and subsequent to his study in Edinburgh he went to Paris, Holland, and Italy.

1765 -
A Course of Lectures -
on the Materia Medica & Practice
of the art, as managed by Man & the
the given at his house
in the City of Philadelphia - Saturday
the 1st of Decr 1765 -
By John Morgan M.D.
Prof. of Med. in the

Front of first admission card to John Morgan's lectures.
 A playing card was used.

While in London in November 1764 he wrote to Dr Cullen in Edinburgh "My scheme of instituting lectures you will hereafter know more of. It is not prudent to broach designs prematurely, and mine are not yet fully ripe for execution. He had discussed his plans with the younger Shippen while they were together in Edinburgh. Shippen had returned to the Province in May 1762 and on November 25 of that year he announced in the *Pennsylvania Gazette* Dr Shippen's Anatomical Lectures will begin to-morrow evening at six o'clock, at his father's house in Fourth Street. Tickets for the course to be had of the Doctor at five Pistoles each and any gentlemen who incline to see the subject prepared for the lectures and learn the art of Dissecting Injections etc. are to pay five Pistoles more. In later years Wistar who became one of the great anatomists remarked "Such was the origin of our medical school." These lectures indeed proved to be the beginning of the broader plan of Morgan which was to found the Medical School of the College and Academy of Philadelphia.

John Fothergill of London had always evinced an interest in the medical affairs of the Province. The Pennsylvania Hospital having been erected he took it for granted that students would resort to it, and well he knew the difficulties that would beset them in the acquisition of a knowledge of anatomy. To remedy this defect Fothergill employed Rumsdyck to execute crayon paintings of the human anatomy.

Shortly after Shippen returned he advised the managers of the Hospital that Fothergill had sent seven cases of anatomical drawings. In a letter to James Pemberton, Fothergill had written and that the means of procuring subjects with you are not easy some pretty accurate anatomical drawings about half as big as the life,

Department of medicine East side of Fifth street between Library and Walnut Streets, 1765 to 1802 Building known as Surgeons' Hall

have fallen into my hands which I propose to send to your hospital. I have recommended it to Dr Shippen to give a course of Anatomical Lectures. He is well qualified for the subject and will soon be followed by an able assistant, Dr Morgan both of whom, I apprehend will not only be useful to the Province in their employments but if suitably countenanced by the Legislature will be able to erect a School of Physic amongst you, that will draw students from various parts of America and the West Indies.

Morgan arrived in Philadelphia early in 1765 and at a special meeting of the Trustees of the College and Academy called for on the 3rd of May, 1765 which was attended by Thomas and Phineas Bond Cadwallader and Redman Morgan presented his plan. He brought with him a letter from the Proprietor Thomas Penn which was indeed laudatory. Dr Morgan has laid before me a proposal for introducing new professorships in the Academy. We are acquainted with what is proposed to be taught and desire that he may be well received and what he has to offer be taken with all becoming Respect and Expedition into your most serious Consideration.

After considering the matter The Trustees entertaining a high sense of Dr Morgan's Abilities and the Honors paid to him by different Learned Bodies and Societies in Europe they unanimously appointed him Professor of the Theory and Practice of Physick in this College. On May 30 and 31 of the same year Morgan gave his inaugural oration "A Discourse upon the

The first wing of the Pennsylvania hospital.

Institution of Medical Schools in America. Morgan was the first physician in Philadelphia to restrict himself to simply prescribing for the sick.

Can any man the least acquainted with the nature of that arduous task, once imagine it possible for me to acquit myself in that station in an honorable or useful manner and yet be engaged in a continued round of practice in surgery and pharmacy as well as physic? On September 23 of the same year Shippen was appointed to the professorship of anatomy and surgery and on September 26 the following announcement appeared in the *Pennsylvania Gazette* "As the necessity of cultivating medical knowledge in America is allowed by all it is with pleasure we inform the public that a Course of Lectures on two of the most important branches of that useful science viz., Anatomy and Materia Medica will be delivered this winter in Philadelphia. In order to render these courses the more extensively useful, we intend to introduce into them as much of the Theory and Practice of Physic, of Pharmacy Chemistry and Surgery as can be conveniently admitted.

From all this, together with an attendance on the practice of the physicians and surgeons of the Pennsylvania Hospital, the students will be able to prosecute their studies with such advantage as will qualify them to practice hereafter with more satisfaction to themselves and benefit to the community." It was signed by Morgan and Shippen.

The first class of students was enrolled in the fall of 1765 and of these ten were graduated with the Degree of Bachelor of Physic in 1768 "the birthday of medical honors in America." The question as to whether the College of Philadelphia or

King's College in New York has the honor of priority in the awarding of medical degrees in this country may now be answered. The degrees of Bachelor of Medicine conferred June 21 1768, by the College of Philadelphia, were the first medical degrees conferred by an institution in the colonies. King's College conferred the same degree for the first time in 1769 and the degree of Doctor of Medicine in 1770. From this it appears that the claim of priority in conferring degrees in medicine must be awarded to the College of Philadelphia while the precedence in conferring the Doctorate must be given to New York. Morgan and Shippen constituted the major Faculty until January 1768 when Adam Kuhn was made professor of botany and materia medica. Kuhn, also, had received a part of his medical training in Edinburgh.

Thus the first medical school in North America was in reality an offspring of the most brilliant school in Europe at that time. The professors had unavoidably acquired an affection and preference for the Scottish school a type of instruction, and for many years the major portion of its professorial faculty received some of their training within the walls of Edinburgh. The University has continued to feel a very close connection to its patron over the seas, and the iron grill over the present entrance contains the thistle. The first medical trustees of the College were the senior Shippen, Thomas Bond, Thomas Cadwallader, Phileas Bond and John Redman.

A very close relationship existed between the college and the Pennsylvania Hospital, and Thomas Bond interested alike in both, would welcome the pupils and graduates of the medical

The University of Pennsylvania, 1806-1839, showing the addition to the left, which housed part of the medical school. The main building was originally built to be Washington's house.

school attending his clinics in the latter and this interest was shared by his colleagues. In this way, the hospital became the first clinical school of the College.

Before another commencement occurred a young physician Benjamin Rush who had also earned his degree at Edinburgh was coming home to become the professor of chemistry in the new school. The average age of the four professors was under 30 years.

The disordered condition of society attendant upon the Revolution disturbed the quiet flow of scientific pursuits. Several of the professors of the Medical School went into the army. Morgan and Shippen successively acted as medical director general and Rush as medical director of the middle department, the latter being one of those who signed the Declaration of Independence.

In these troublesome times of new freedom the Charter of the College of Philadelphia was revoked by an act of the Legislature in November 1779. This was the result of a feeling that the institution, being of colonial origin and patronage, needed thorough reorganization in order to place it on a basis harmonizing with the régime of Independence. The property of the College was transferred to a new institution.

The institution which took the place of the College of Philadelphia was called the University of the State of Pennsylvania. The trustees of the new school at once directed attention to the medical department. They requested the several Medical Professors in the mean time to proceed in their lectures as before. Dr Shippen was the only one of the professors who at once accepted the position he had held in the Faculty of the College. Great difficulty was encountered in forming a faculty and in October 1781, Thomas Bond was requested to unite Lectures on the

Theory and Practice of Physic with his course of Clinical Lectures until such time as a professor of that branch of medicine be appointed and undertake the business. This state of irregularity existed until November, 1783 when the former status of the professors was accepted by them.

Friends of the former College were successful in having the charter and property of the college restored in 1789, the new institution however retaining its position as a University, with its endowment from confiscated estates.

There existed then two medical schools with a somewhat interlocking faculty. Shippen taught in both schools, Kuhn only in the University, while Wistar took the chair of Chemistry at the College. James Hutchinson became professor of chemistry in the University and Rush became professor of theory and practice in the College. Morgan died at this time. The College decided to abolish the degree of Bachelor of Medicine and to confer only the Doctorate.

The field for two establishments proved to be too restricted, and after party spirit had subsided and factional strife lulled to rest it was realized that in union there would be additional strength. An amicable adjustment was brought about in September, 1791. It was agreed that the name of the united school was to be "The University of Pennsylvania." In the inaugural lecture delivered by Benjamin Rush in November 1791, he said "I should do violence to my feeling should I proceed to the subjects of the ensuing course of lectures, without first congratulating you upon the union of the two Medical Schools of Philadelphia, under a Charter founded upon the most liberal concessions by the gentlemen who projected it. By means of this event the ancient harmony of the different professors of medicine

The University of Pennsylvania, 1829 to 1873. On the left is Medical Hall.

will be restored and their united efforts will be devoted, with accumulated force towards the advancement of our Science.

The new faculty consisted of the professors of both schools. The announcement gave the professors and their subjects as follows:

Anatomy, Surgery and Midwifery	William Shippen, M.D. Casper Wistar, M.D. Adjunct.
Theory and Practice of Medicine	Adam Kuhn, M.D.
Institutes of Medicine and Clinical Medicine	Benjamin Rush, M.D.
Chemistry	James Hutchinson, M.D.
Materia Medica and Pharmacy	Samuel P. Griffiths, M.D.
Botany and Natural History	Benj. Smith Barton, M.D.

In 1805 a change was deemed to be expedient in the chair which had been held so long and honorably by Shippen. Surgery had remained in association with anatomy and obstetrics. Philip Syng Physick, who since 1794 had been one of the surgeons to the Pennsylvania Hospital, was elected professor of surgery. At this time the mother school in Edinburgh still combined anatomy and surgery in one chair. He filled the chair for 14 years, at which time he became professor of anatomy. One of his last major operations was one on Chief Justice Marshall for the removal of a stone in the bladder. Physick truly deserves the appellation so frequently applied to him "Father of American Surgery."

Shippen died in 1808. He had been a great teacher and had played a very important rôle in the early history of Philadelphia medicine. He was succeeded by Casper Wistar who at first taught both anatomy and midwifery but in 1810 the combined chair of anatomy and obstetrics was

divided. Thomas Chalkley James was elected professor of midwifery but it was not until 1813 that attendance upon his lectures was made obligatory for graduation. Wistar died in 1818. He was an ardent advocate of the use of models in teaching. His extensive group of models and specimens were presented to the University and were for years styled the Wistar Museum. It was greatly enlarged by two of Wistar's illustrious successors, Horner and Leidy. In 1819 the chair of surgery was awarded to William Gibson, who at the time was professor of surgery in the University of Maryland whose School of Medicine was founded by Pennsylvania's first medical graduate John Archer Dewees, who had been adjunct professor of obstetrics, succeeded James in 1834. He was the first authoritative writer on this subject in America and may truly be regarded as the "Father of American Obstetrics."

With the separation of the important chairs into individual units, the School of Medicine of the University had begun the second period of its development. Those who succeeded maintained the high standard already set for them. The names of Horner, Leidy and Penrose, of Hare and Coxe of Agnew and John Ashhurst of George B. Wood, Horatio C. Wood, of the William Peppers, Stille and Osler of Mills and the Norrises of Hodge, Goodell and R. A. F. Penrose of Guilteras, Durhing and many others fill an important niche in the history of American Medicine in the nineteenth century.

Philadelphia maintained its reputation as the medical center of the country. The splendid clinical instruction which had been begun in the Pennsylvania Hospital in 1766 by Thomas Bood, in connection with the medical lectures at the College was expanded. The instruction was given at the bedside and in the clinical amphitheater.

Clinical opportunities were also afforded at the Philadelphia Almshouse (Blockley) now the Philadelphia General Hospital. It had gone into operation before the Pennsylvania Hospital, but not strictly as a hospital. In it was established the first obstetrical clinic for students, as early as 1770. For periods of time students were excluded but after 1805 every successive year found the prejudices which had operated so long, more and more removed. The Managers with each succeeding year were seized with an active desire to foster and promote any method which contributed to the hospital's usefulness as a teaching institution.

In 1873 William Pepper, Jr. had the foresight to realize the importance of having a hospital

which should be an integral part of the Medical School. Largely through his efforts the present hospital of the University of Pennsylvania was built, the first hospital controlled by, and built for, a school in America.

Shippen's lectures had been delivered for years in apartments built in the rear of his father's home on Fourth Street. The other lectures were first probably given in the old Academy Building. The first building especially built for the use of the Medical Professors was situated on Fifth Street and was called Surgeon's Hall.

In 1802 the Medical School was partly moved to a former state building built for the president on Ninth Street between Chestnut and Market Streets, and in 1806 an additional building was built on Ninth Street, and it was further enlarged in 1817. The school grew and accommodations rapidly became inadequate. The Trustees ordered that all buildings be removed and in 1829 built what for many years was known as Medical Hall. It was not until 1873 that the Medical School was moved to the present University site west of the Schuylkill River.

FURTHER OBSERVATIONS ON THE ROLE OF BILE IN HIGH INTESTINAL OBSTRUCTION

To the Editor In a previous paper Benedict, Stewart and Cutner¹ reported the results of certain experiments on the rôle of bile in high intestinal obstruction. Although the results were not entirely conclusive they seemed to indicate that when obstruction of the intestine was so high that no bile could be reabsorbed, benefit might be derived from administration of bile below the obstruction.

In the course of further experiments on high intestinal obstruction in dogs, all bile was diverted from the intestinal tract by cholecystostomy and ligation of the common bile duct. Obstruction of the intestine was carried out a week later by completely severing the bowel just below the ampulla of Vater by inverting the proximal end and sewing a catheter into the distal end for use as an enterostomy. Through this catheter sufficient normal saline was administered twice a day to maintain water balance and normal blood chlorides. The cholecystostomy catheter was connected to a small rubber balloon and the bile withdrawn once a day.

One such animal survived for 38 days, at which time malnutrition probably was the most important factor in causing death. At no time was there any evidence of bile in the vomitus or stools, and autopsy revealed no accessory bile ducts. As this period of survival is longer than any heretofore reported in so high an intestinal obstruction the experiment would seem to disprove the theory that the presence of bile

either above or below an obstruction of the intestine is a factor of any significance in the length of survival of the animal. Death in high intestinal obstruction, when the water and chloride balance is maintained, is probably due largely to malnutrition.

NEW MUSCLE-SPLITTING INCISION FOR RESECTION OF THE UPPER THORACIC SYMPATHETIC GANGLIA—A COR RECTION

In publishing this article in the March, 1933, issue, pages 651-657, a regrettable error was made which disarranged the order of the illustrations, certain of the plates appearing with incorrect legends. To correct the error the following changes should be noted: The plate appearing as Fig. 3 should be Fig. 1; Fig. 7 should be Fig. 5; Fig. 4 should be Fig. 3; Fig. 1 should be Fig. 4; Fig. 5 should be Fig. 7.—EDITOR.

JOHN B. MURPHY

Material is being collected for an authorized biography of Dr. John B. Murphy. If any reader of this JOURNAL has in his possession letters from Dr. Murphy, knowledge of facts concerning his life, or any other data, it would be appreciated if they were sent to the Editors. All material will be returned promptly and the source credited.

A DIFFERENTIAL DIAGNOSIS BETWEEN CERTAIN TYPES OF INFECTIOUS GANGRENE OF THE SKIN

WITH PARTICULAR REFERENCE TO HEMOLYTIC STREPTOCOCCUS GANGRENE AND BACTERIAL SYNERGISTIC GANGRENE¹

FRANK L. MELENEY M.D., F.A.C.S. NEW YORK
Assistant Professor of Surgery, Columbia University

IN recent years there has been considerable interest in the problem of gangrene of the skin due to the invasion of micro-organisms. The literature in this field indicates that there has been great difficulty in the minds of some observers regarding the proper classification of these disorders. Many authors have reported late diagnosis late institution of treatment, extensive destruction of tissue long hospitalization and high mortality. This is due partly to the fact that these diseases (except gas gangrene) are relatively rare so that few observers have been able to report more than a single case. Confusion has further resulted from the fact that bacteriological studies have frequently been made so late in the course of the disease that it has been difficult to appraise the importance of the bacteria which have been found and frequently cultural methods have been used which were not suitable to reveal the significant organisms. It is with the purpose of clarifying this subject to some extent, that the present paper is written because the treatment of the various groups differs markedly and a delay in diagnosis results in a delay in instituting the proper treatment.

In infectious gangrene, bacteriological studies are essential if we are to learn anything about the pathogenesis of these infections and

improve our method of treatment. These studies should be made early in the course of the disease and cultures should be taken from various parts of the lesion particularly in the zone of advance. Anaerobic, as well as aerobic methods must be employed and culture media be used which is suitable for the growth of any organisms which may be present. It is obvious that this cannot be done in the great majority of cases, for many of them are seen either at home or in the office or in hospitals which are not fully equipped to make a complete bacteriological study. Furthermore the time required for the complete bacteriological analysis of any given case makes the study of little value as a basis of treatment for that particular case, particularly if the onset is sudden and the course is rapid. For all of these reasons it is essential that there should be a clinical differentiation by which any one seeing a case for the first time may recognize it at once and promptly institute the proper treatment. An attempt has been made, therefore in the following paragraphs to give a practical clinical differentiation between certain types of infectious gangrenous processes of the skin and subcutaneous tissues.

The most important division of these cases is into acute and chronic groups. In the former a diagnosis should be made within a few

From the Bacteriological Research Laboratory of the Department of Surgery, College of Physicians and Surgeons, Columbia University and the Presbyterian Hospital, New York, New York.

hours. In the latter it may be safely made within a few days.

ACUTE GANGRENE

Acute infectious gangrene may be divided into two subgroups of great importance. These differ in so many features that they ought not to be confused. The first is relatively common, namely gas gangrene. It was seen during the war by every army surgeon. This is so well known in this generation that it is hardly necessary to go into details with regard to it in this paper except to differentiate it from the other groups. Let us hope that the coming era of World Peace under the League of Nations and the Pact of Paris will make it a rare disease.

GAS GANGRENE

Gas gangrene has recently been excellently reviewed by Wan and by Davison and in individual cases have been reported by Linton, Shearer, Sarlin, Maes and Butler. Gas gangrene not infrequently develops in a deep punctured or lacerated wound which extends down into muscle and carries with it such foreign bodies as clothing, missiles, powder or street dirt. A large proportion of the cases of gas gangrene in civil practice follow compound fractures. Likewise occasional cases develop after operation following the amputation of gangrenous lower extremities in diabetics or arteriosclerotics. The possibility of its development in these cases should always be kept in mind because certain precautions may be taken to prevent its occurrence and its early recognition is essential for its successful treatment.

Symptomatology. The onset of the disease is usually associated with an abrupt rise in temperature and pulse rate. The pulse approaches 120 and the fever reaches 103 to 105 degrees. There is general malaise, marked prostration and restlessness as well as apprehension. There is usually an increase of pain in the wound. This may be masked if the wound has been painful from the first. An examination of the wound usually reveals swelling and edema with redness and acute tenderness. Gentle pressure on the margins of the wound usually produces a sanguinopurulent exudate in which gas bubbles may

be seen. A smear made from this exudate will almost invariably reveal large numbers of large gram positive bacilli. Gentle palpation of the tissues may reveal crepitus, but this may not be appreciated in the early stages. An X-ray film will frequently demonstrate gas in the tissues even before it can be felt. To an experienced observer with a keenly discriminating sense of smell there is a characteristic acid or 'mousy' odor.

When the infection has gained a foothold it spreads rapidly; the patient becomes very ill; fever remains high, the pulse rate increases, and crepitation around the wound is evident. This may advance appreciably from hour to hour. The spread of the disease is chiefly in the muscles. It may be confined to a single muscle from the wound margin up to its origin, leaving the neighboring muscles free but usually it spreads up the neighboring groups as well to a varying extent from the wound. The skin at the wound margin becomes first red and then dusky. The redness and edema spread for a moderate distance around the wound but not extensively. Gradually the skin at the margin becomes dark and necrotic while the reddened area away from the margin takes on a yellowish brown or bronzed tint. Gangrene of the skin is generally limited to the margin of the wound and if the disease spreads extensively in the muscle the gangrene of the skin slowly advances but it does not appear in isolated patches away from the margin. In untreated cases gas gangrene is rapidly progressive and almost invariably ends fatally.

Etiology. The gas gangrene organisms are anaerobic bacteria which differ from one another in their cultural characteristics and in the specific toxins which they form. There are four different species which are pathogenic for man and although they rarely occur in pure culture in gangrenous processes, they are believed to be able, alone, to produce the general and local symptoms of gas gangrene and their specific toxins may cause death. However, they are frequently associated with other organisms and there may be a synergistic action enhancing the virulence of the pathogenic anaerobes or the associated organisms. The most common of the gas gangrene organ-

isms is *Bacillus aerogenes capsulatus* (*Clostridium welchii*). The others are *Bacillus oedematis* (*Clostridium novyi*) *Vibrio septique* (*Clostridium oedematis maligni*) and *Bacillus sordelli* (*Clostridium oedematoides*). The 3 last are more rarely found and if any one of these organisms is present the local signs vary somewhat from that already described in that there is more oedema and induration of the tissues and less gas formation.

Treatment With the earliest signs of this disease a stained smear of the exudate should be made if possible. If the signs are unmistakable or if in doubtful cases large gram positive bacilli are numerous in the smear immediate operative interference is of the utmost importance. This procedure should not wait upon the cultural determination of the organisms. The wound should be completely excised and all foreign bodies and all necrotic tissue should be removed. Individual muscles should be explored and any inactive or devitalized muscle tissue should be removed. Anti gas gangrene serum should be used in large quantities. The serum which is now available is more potent and more concentrated than that which was formerly prepared and is effective against all of the known pathogenic gas gangrene organisms as well as tetanus. Concentrated monovalent and polyvalent sera are now available in "therapeutic doses." Depending on the severity and extent of the infection one or more "therapeutic doses" should be given intravenously as soon as the diagnosis is made and repeated every 8 hours until there is definite subsidence of local and general symptoms. If it is not possible to determine by culture what organisms are present, a polyvalent serum should be used but if an analysis of the flora of the wound has been made the specific antiserum should be administered in subsequent treatments.

There is a considerable difference in opinion as to whether amputation should be done in these cases. In certain regions of the body amputation is out of the question. However, even in a good many cases in which amputation may be done quickly and safely, if the disease is diagnosed soon after its develop-

ment, amputation is not indicated. Adequate opening of the wound and removal of dead tissue and the administration of serum is frequently effective and results in the subsidence of the process. Although it is likely that amputation has been done in the severer cases the statistics would seem to indicate that the mortality in amputated cases is not appreciably lower than in those in which that procedure is not employed.

HEMOLYTIC STREPTOCOCCUS GANGRENE

Since the author's first report (60) in 1924 this infection has been described by Gage and by Jen as well as in briefer reports by Mainzer Bate Fallon and Bettmann and by the writer (61 62). This disease may occur following a deep wound but is more likely to follow a much more trivial injury. Sometimes the injury is so light that it appears to be a spontaneous infection but in general there is a history of a superficial injury of the skin a scratch a cut, or a hypodermic injection. It generally occurs on the extremities but may involve any part of the body. In the earlier literature some of these cases have been described as phlegmonous or gangrenous erysipelas but there are striking differences between this disease and erysipelas which will be brought out later.

Symptomatology The disease is characterized by the sudden onset of pain and swelling at the site of injury. The part becomes red, hot, swollen and heavy and while at first it may be very painful it later becomes numb or anesthetic. The redness spreads rapidly during the first 2 days and may be very marked but the margins fade out into the normal skin and are not raised as in erysipelas. The temperature generally does not rise over 101 to 102 degrees except in rare instances when the illness is ushered in with a chill. Then the temperature may reach 103 to 104 degrees. On the other hand the pulse rate is rapid frequently approaching 120. Prostration is marked but instead of irritability, there is usually a marked lassitude on the part of the patient. He becomes indifferent to his surroundings and has a total lack of appreciation of the severity of his illness. On the second third or fourth day the pathogno-

monic sign of the disease appears. *This should be watched for in any acute fulminating inflammation.* The sign is a dusky coloring of the skin appearing as a small purplish patch with irregular and ill defined margins. It may be some distance from the portal of entry. It has a bluish tinge which makes it distinct from the brilliant redness of the surrounding skin. At the same time a large blister or bulla may appear over this dusky area or some where else upon the red surface. These areas may extend very rapidly and changes in them may be seen from hour to hour. If proper treatment is not instituted at once other dusky patches may develop nearby and these areas may later fuse so as to form a large plaque of gangrenous skin. In untreated cases about the seventh, eighth, or ninth day if the patient survives, this necrotic skin becomes more sharply demarcated from the rest of the skin and a little later partial separation takes place along the edges. While the gangrene is developing the diffuse redness continues to spread. The patient becomes more and more prostrated fever ranges around 101 to 103 degrees, and metastatic foci may develop in the lungs in joints or elsewhere in the body. Frequent sites for these metastatic lesions are the subcutaneous tissues at pressure points or elsewhere. These metastases frequently form with very little redness but with a definite swelling and rapid formation of pus. In a few untreated cases the process comes to a standstill about the end of the second week, the slough separates and large plaques of necrotic subcutaneous fat may separate beneath a relatively normal skin. But most untreated cases go on to rapidly overwhelming toxemia with septicemia extensive metastases, and death. On the other hand if proper treatment is instituted early the whole process generally comes to an abrupt standstill and cases thought to be hopeless go on to rapid resolution and recovery. In the series of cases reported from China the mortality was 20 per cent but in the cases that I have seen in this country the mortality has approached 50 per cent. This higher mortality may indicate a difference in resistance to the hemolytic streptococcus between Chinese and Americans or it may be simply a question of late

recognition and late treatment. In the series which we reported from China the disease was so common that earlier recognition of it was possible. When an adequate operation was promptly performed, all of the cases which were not *in extremis* on admission responded satisfactorily to the treatment. With most of the cases which the writer has seen outside of the hospital diagnosis has been made late and the treatment has been delayed or inadequate. Under these circumstances the prognosis must be guarded for in such cases septicemia is common and metastases frequent.

This disease is essentially a gangrene of the subcutaneous tissue with secondary gangrene of a part of the overlying skin resulting from a thrombosis of the skin arteries which pass through the sloughing subcutaneous fat. The subcutaneous gangrene may extend for a long distance beyond the area of skin gangrene. Through this extensive subcutaneous slough patent blood vessels may be found supplying the relatively normal skin.

Etiology. The hemolytic streptococcus is always found in these cases and in the great majority of cases it may be found in pure culture out in the advancing margin of the subcutaneous necrosis. Beyond the limit of subcutaneous necrosis there is a zone of redness and edema which yields a sterile culture. This is in striking contrast to erysipelas for in the latter disease streptococci are most numerous in the advancing margin of redness and even beyond it in relatively normal skin. It must be assumed that in hemolytic streptococcus gangrene there is a toxin widely diffusible in the skin and subcutaneous tissues which gives rise to the rapidly spreading zone of redness. In the early stages the hemolytic streptococcus is also found in pure culture in the dusky areas of purplish discoloration and in the fluid of the blisters or bullae. Later when the gangrene separates, other organisms may contaminate the field but usually do not spread widely. It is almost certain that these associated organisms play no part in the development of the disease and that it is, in fact, a pure hemolytic streptococcus infection. The rapidity of its development and the extensive necrosis which it causes, suggest that

the peculiar characteristics of the onset of the infection may be due to a hypersensitivity similar to the Schwartzman phenomenon (82) or the Arthus phenomenon (3). Certain cases seem to illustrate one type and other cases the other. The allergic etiology has not yet been proved beyond question and it is difficult to prove because according to Schwartzman streptococci can produce the secondary necrotizing effect but cannot produce the primary sensitizing effect of the phenomenon. The sensitizing phase may be and probably is non-specific. Another theory is that the organisms have some special predilection for the subcutaneous tissues or produce a ferment which acts quickly upon the subcutaneous connective tissue and fat. However efforts which have been made to demonstrate such ferments have proved unsuccessful. These tests have not been done, however with recently recovered strains of the organism.

Treatment. Surgery should not be delayed an hour after the diagnosis has been made. Contrary to the usual procedure either in erysipelas or in streptococcus cellulitis of the ordinary kind, longitudinal incision should be made at once through the gangrenous area and should extend in both directions just beyond the limits of the subcutaneous necrosis. Incision should be radical rather than conservative and long single incisions serve the purpose better than multiple small incisions in any given axis. The effect of these incisions is to relieve tension and at least partially to drain the involved area. This improves the blood supply and turns the flow of drainage away from the advancing margin. After operation hot water soaks or hot poultices should be applied until the cellulitis subsides. This usually requires 2 to 3 days. Then Dakin's fluid should be applied by means of tubes or frequently changed compresses to favor the rapid separation of the slough. Each day as much of the slough as can be removed without bleeding should be cut away. If incisions are early and adequate, the process will promptly subside and patients who look desperately ill when first seen, will show remarkable improvement and go on to complete recovery. But if operation is delayed for 24 hours after the pathognomonic signs appear,

the chances of recovery will be greatly diminished and the extent of subsequent skin necrosis will be greatly increased.

Differential diagnosis. Fulminating types of gangrene generally fall either into the gas gangrene group or into the hemolytic streptococcus gangrene group. They should not be confused for in the former the injury is almost always deep and the invasion is largely in the muscular layers with gas formation and crepitation both in the muscle and in the subcutaneous tissues while the skin is relatively free. In hemolytic streptococcus gangrene on the other hand the injury is usually superficial and the spread is almost always in the subcutaneous tissues with early involvement of the skin and without any crepitation. In gas gangrene the general symptoms are alarming and the local signs relatively mild. In hemolytic streptococcus gangrene the local signs are alarming and the general symptoms relatively mild. While both infections are primarily due to specific organisms infection may be rendered more severe by the association of other bacteria. However in the case of gas gangrene these organisms generally gain a foothold at the same time or before the organisms of the gas gangrene group whereas with hemolytic streptococcus gangrene the hemolytic streptococcus is alone responsible for the initiation of the infection and secondary contaminants only grow after there has been a break at the margin of the gangrenous portion of the skin. Stained smears of the exudate in gas gangrene show many gram positive rods while in streptococcus gangrene the exudate contains only gram positive diplococci.

Hemolytic streptococcus gangrene has been frequently confused with erysipelas which is likewise caused by a hemolytic streptococcus but certain features sharply distinguish them. In both diseases, the onset is sudden but in erysipelas the general symptoms overshadow the local there is usually a chill and a sudden rise of temperature to 103 to 105 degrees and the patient becomes apprehensive or irritable. In hemolytic streptococcus gangrene the local symptoms overshadow the general, a chill is rare, the temperature does not often go as high as 103 degrees. The patient is indifferent rather than apprehensive

and dull rather than irritable. In erysipelas the redness starts in a small area and spreads perceptibly but rather slowly with a red raised margin at least in a part of its periphery. There is very little swelling of the part and the tissues are soft. As it spreads, the center becomes pale again. In hemolytic streptococcus gangrene the onset is sudden, the affected part very rapidly becomes swollen and heavy swelling and redness may spread up the whole extremity or widely over the body in 24 to 48 hours but the margin of redness is not raised and is generally indistinct as it fades off into normal skin. The center does not become pale but bullæ form and dusky areas appear on the third fourth or fifth day and go on to frank gangrene. Lymphangitis and lymphadenitis are rare but phlebitis is fairly common. In erysipelas, organisms may be cultivated at and beyond the spreading margin (95) but not in the center while in hemolytic streptococcus gangrene there is a wide zone of redness in which cultures yield no growth but organisms are found in the blisters or bullæ and in the subcutaneous tissues out to the limit of the necrotic zone. Erysipelas may develop at any time during the course of this disease just as it may develop from any hemolytic streptococcus wound. The writer has seen it just three times in the 45 or 50 cases of hemolytic streptococcus gangrene which have come under his observation.

It seems likely that Fournier's cases of gangrene of the scrotum penis and vulva belonged to the hemolytic streptococcus gangrene group. When he made his early reports, the cause was not known but some of Fournier's pupils who studied the disease in later years believed the streptococcus to be responsible. Bodin however reported a case of gangrene of the vulva in which there were not only streptococci but fusiform bacilli and spirilla which he thought were significant. Millan and Natville believe that they have found a specific organism of the *Bacillus proteus* group which produces gangrene of the skin in animals and as they think, the important factor in human gangrene of the skin. However in 13 of 14 they found it associated with a streptococcus (not further classified) and they admit that they believe that the

streptococcus opened the door to the invasion of this organism. They found their organism in cases which were not at all alike clinically. Some were acute and others chronic. The acute cases which they describe may very well fall into the hemolytic streptococcus gangrene group. The organism which they found seems more likely to have been a secondary invader. Culturally it can hardly be distinguished from other organisms of the *Bacillus proteus* group. It grows aerobically and profusely in all media. It spreads very quickly over a blood agar plate and when present makes the recovery of associated organisms very difficult. This prolific growth would lead one to believe that when it is not found it is surely absent from the lesion. This can not be said of organisms more difficult to grow or organisms requiring anaerobic environment. The fact that Millan's organism was not recovered more often in the series of streptococcus gangrene cases seen by the writer in China which were previously reported (66) and is not often found in gas gangrene would seem to indicate that it is not a common or an important factor in the production of either of these forms of gangrene. Although it may occur more often in gangrene of the scrotum than in gangrene elsewhere because of the proximity of the anus, it was absent in the two cases of fulminating gangrene of the scrotum which the author has seen, both of which were typical hemolytic streptococcus gangrene. Bodin also in reviewing the subject of fulminating gangrene of the genitals, does not concede the theory of Millan and Natville that their *Bacillus gangrene cutis* (which was absent in his case) is of any significance as the cause of fulminating gangrene of the genitals.

The differential diagnosis of these acute diseases may be conveniently summarized in chart form (Table I)

CHRONIC GANGRENE

Cases of chronic infectious gangrene may be classified into three or four important subdivisions. Their differentiation is clinically more difficult than that of the acute cases. Each type has a number of distinguishing characteristics although in some instances the diagnosis may have to await a bacteriological

TABLE I.—DIFFERENTIATION OF ACUTE CASES

Name	Etiology	Symptomatology	Pathology	Treatment
Gas gangrene	Deep wound into muscle. Gram positive spore forming anaerobic rods. Early development of various kinds of associated bacteria.	Sudden onset. Profound general symptoms. High fever rapid pulse; apprehension, irritability. Relatively mild local signs. Limited redness, swelling and crepitation. Blisters and necrosis. Browning of skin. Limited gangrene.	Extensive death of muscle. Fibers broken by gas formation. May spread whole length of a single muscle. Eudata loaded with gram positive rods. Relatively few pus cells. Negative chemotaxis for W B C.	Prompt operation. Removal of all foreign bodies and dead tissues. Complete debridement of wound. Early administration of large quantities of penicillin or specific serum.
Hemolytic streptococcus gangrene	Superficial wound. Pure culture hemolytic streptococcus. No other bacteria or late occurrence of a few other species after gangrenous skin has separated.	Sudden onset. Relatively mild general symptoms. Low fever but rapid pulse. Limitless indurated anesthetic. Alarming local signs. Extreme redness and edema without sharp margins. Irregular dusky areas on third, fourth, or fifth day. Blisters and bullae. Rapidly developing extensive gangrene.	Extensive necrosis of subcutaneous tissues with a wide zone of sterile edema beyond the limits of necrosis. Heavy exudation of fluid and polymorphonuclears at first and later large mononuclear phagocytes. Bacteria found all through the necrotic subcutaneous fat and in the blisters and bullae. Thrombosis of some of blood vessels to overlying skin which becomes gangrenous.	Prompt operation. Long incisions to the limits of the subcutaneous necrosis. Release of all tension. Removal of necrotic tissue as soon as possible with minimum of bleeding. Hot applications of moist heat until subsidence of cellulitis. Skin grafting if defect is extensive.
Frostbite	Superficial wound. Pure culture of hemolytic streptococcus. No associated bacteria.	Sudden onset. Profound general symptoms. Chills. High fever. Rapid pulse. Apprehension, irritability. Slightly but steadily spreading area of redness with little or no swelling. Sharp raised margins.	Slight swelling and thickening of skin. No edema of subcutaneous fat. Bacteria in and beyond advancing area and not in center of lesion.	No operation. Soothing local applications. Ultraviolet light. Serum in severe cases.

analysis. Fortunately the progress of these diseases is slow and time is given for a bacteriological study which may be used as the basis for treatment. While all of these groups are characterized by some distinctive clinical features it seems certain that in each type the characteristic lesions are produced not by one organism as in the acute cases but by a special combination of two or more organisms. These diseases may therefore be called synergistic infections. They may be conveniently named as follows: (1) postoperative progressive bacterial synergistic gangrene of the abdominal or chest wall, (2) gangrenous impetigo (ecthyma) (3) fusospirochetal infection of the skin, (4) amebic infection of the skin.

POSTOPERATIVE PROGRESSIVE BACTERIAL SYNERGISTIC GANGRENE

One of the most striking examples of chronic gangrene of the skin is that which occasionally follows the drainage of a deep abscess either in the peritoneal cavity or in the chest. Considerable interest has been taken in this condition since 1924 when Cullen described a case which was thought at the time to be first on record. It has been reported so frequently since then that there seems to be no doubt that it occurred frequently before that time and was reported but the titles as they appear

in the *Index Medicus* or *Surgeon General's Library Index* fail to reveal these reports definitely and they are obscured by the great mass of literature on the general subject of gangrene. Since Cullen's publication cases have been reported by Brewer and Meloney, Alexander Shipley, Gillespie, Hellström, Freeman, Mayeda, and more recently by Ballin and Morse (Case 4), Lynn, Meloney (63), Baker and Terry, Horsley (Case 1), Carol and Kappis (Case 3). In this group also belong the cases of Christopher, Ballin and Morse (Case 2), Poate and Patterson all of which involved the chest wall following the drainage of an empyema. A few cases have been reported which developed spontaneously, e.g., Luckett and Kappis (Case 1), or after clean operations in poorly nourished tissue, e.g., Kappis (Case 2) or after operations on frankly infected tissue, e.g., Probst and Seelig. Inasmuch as anaerobic cultures were not made in these cases and the clinical course is not perfectly clear we cannot say with certainty whether or not they belong in this group but it would seem to be possible for the organisms causing this infection to be introduced into the tissues of the abdominal wall from without rather than from a deep abscess.

Symptomatology. In the majority of the cases which have been reported the gangrene has followed the drainage of a peritoneal

abscess. It usually begins to appear about the end of the first or second week after operation either as an infection of the whole wound or as a localized induration about retention sutures. At first the wound becomes red, swollen and tender. Within the next few days the wound margins or the stitch holes develop a carbuncloid indurated appearance. The center of activity becomes purplish in color while the outer zone takes on a brilliant red tint. The whole region becomes exquisitely tender. *This symptom is an outstanding feature of the disease.* Within a few days the purplish areas become frankly gangrenous. The color of the dead skin changes to a dirty greyish brown and the surface is dull like uede leather. The purple zone spreads outward into the red and as it does so the skin becomes swollen and stands up above the normal skin level. The central side of the purple zone toward the gangrene is sharply defined but on the outer side it fades off into the red zone which slowly advances in all directions. The gangrenous skin is firmly adherent to the purple zone and there is very little undermining of normal skin. As the process advances, the gangrenous skin liquefies on its inner margin so that as it encroaches on the purple zone and the circumference of the whole lesion enlarges the width of the three zones remain fairly constant. As the inner margin of the gangrenous zone liquefies it leaves exposed a base of granulation tissue which gradually enlarges. The destruction of the dermis is not always complete and here and there some deep islands of epithelium from sweat glands or hair follicles may start patches of regenerating skin epithelium. Usually there is very little general reaction manifested either by fever or anemia and the patient remains in fairly good general condition although as the process goes on he is gradually worn down with discouragement and pain. The reports of all but the most recent cases indicate that the true nature of the lesion was not recognized until there had been extensive destruction of the skin. In several cases practically the whole surface of the abdominal wall, and in one case the whole back became involved. In a number of cases the lesion spread downward from the abdomen to the thigh.

Etiology. In most of the cases reported in the literature only routine bacteriological studies were made. They yielded a variety of organisms none of which seemed to be of special significance. Special methods, however were used in the study of the second case reported by Brewer and the writer (11) as well as in a subsequent case (63) and since they yielded identical results the findings seem to be significant. In the study of these cases an effort was made to determine all of the organisms present not only in the gangrenous tissue but in the spreading periphery of the lesion. This was possible in the first case when, after conservative measures had been employed unsuccessfully a wide excision of the lesion was done and the specimen taken immediately to the laboratory. Multiple cultures were then made from the subcutaneous fat at the periphery of the lesion inward toward the gangrenous zone. A micro-aerophilic non-haemolytic streptococcus was found in pure culture at the periphery of the lesion not only in the red zone but just beyond it in the relatively normal tissues at the very margin of the specimen and far from the area of gangrene. In the gangrenous tissue itself this organism was found to be associated with a haemolytic *Staphylococcus aureus*, and a diphtheroid bacillus. The diphtheroid bacillus was entirely non-pathogenic for animals when injected alone or with either of the other organisms. When the streptococcus and staphylococcus were injected in pure culture into animals no lesion was produced but when half doses of each organism were combined and injected a gangrenous process developed which spread during the course of 3 or 4 days and simulated to a considerable degree, the lesion in man. With this demonstration that these organisms could do something together which they could not do alone, the theory was advanced that the disease was the result of a synergistic action of the two organisms, the non-haemolytic micro-aerophilic streptococcus being the essential organism in the zone of advance, in some way preparing the ground for the gangrenous action of the combined organisms. When the second case appeared, an opportunity was given in a single case to study two lesions both of which yielded the

same result. Again the micro-aerophilic non-haemolytic streptococcus was found in pure culture at the periphery and it was associated with a haemolytic *Staphylococcus aureus* in the gangrenous area. No diptheroids were found. The synergistic experiments already described were repeated in animals over and over again. This seemed to offer definite confirmation of the theory of bacterial synergism as the cause of this disease. It is hoped that other investigators using the same methods elsewhere will endeavor to confirm the findings. It should be remembered that this micro-aerophilic streptococcus is not a strict anaerobe and will grow aerobically after a number of artificial transplants in media with a reduced oxygen tension and it is quite possible that in some cases it may be obtained aerobically from the exudate at the gangrenous margin of the lesion even on primary culture. I believe that this has been done in those cases which were reported to have yielded a non-haemolytic streptococcus. But when a study is made of the periphery of the freshly excised lesion in the red zone it is likely that this organism will only be obtained by anaerobic methods. It corresponds to *Streptococcus evolutus* of Prévot (76).

In the 2 cases just summarized the organism which Midan and Nativelle described was not found. This would seem to indicate definitely that it is not a causative factor in this disease. It may however contaminate the wound just as *Bacillus coli*, *Bacillus welchii* or any other intestinal organism may occur in a wound without necessarily taking part in the infection. (See reports of Cases 1 and 2 in which this occurred and Case 3 in which it did not occur.)

Owing to the fact that a number of authors (e.g., Cole and Heideman) have reported the presence of amœbæ in similar lesions a careful study made in all 5 of these specimens by three different well trained parasitologists and in none of the 5 cases personally seen by the writer has there been anything suggestive of the presence of amœbæ in the tissues or in the exudate. The writer believes that this lesion may be secondarily contaminated with the bacillus which Milian has described and also with amœbæ but the evidence is strong that

these are not essential for the production of the lesion. Practically all of these cases have occurred following the drainage of a deep abscess either in the peritoneum or in the chest. In the abdominal cases the organism presumably came from the intestine as it is a common inhabitant of the alimentary canal. In the chest cases the original source of the streptococcus would seem to be either from the mouth or from infected emboli which were thrown off from thrombosed vessels in the peritoneum.

Treatment. In most of the cases which have been reported the wounds were partially closed by suture. This tissue tension in the presence of contamination may have favored the establishment of the infection. This suggests as a prophylactic measure that all skin wounds be left unsutured when peritoneal abscesses or chronic empyemas or lung abscesses are drained. The chronicity of this condition has afforded the opportunity of trying to cure it by many methods. Certain of the reports reflect the ingenuity and persistence of the surgeons in using all sorts of chemical and serological agents both generally and locally in the face of a baffling problem. In almost every case conservative methods including local excision of the gangrenous margins have failed to check the advance of this process but radical removal of the lesion including the outer zone of redness, either with the knife or with the cautery has almost invariably resulted in prompt disappearance of the disease. The defect left by this radical operation has then very quickly responded to skin grafting. In the present state of our knowledge with regard to these infections this treatment should be instituted within a few days after the diagnosis has been made. When we learn something more about the interaction of these organisms and find some way to interfere with their action perhaps more conservative measures will be effective. The writer prefers the knife to the cautery because there is less injury to the tissues and healing does not have to wait upon the separation of the tissue which has been destroyed by the cautery. There is very little to choose between the scalpel and the 'radio knife'.

Fig. Case. Note the two separate areas of gangrene firmly adherent at the scalloped margin. Immediately beyond that is the raised purple zone merging into a red zone which fades into normal skin.

Recent cases. During the past year the writer has seen three more typical cases of this kind which will be briefly reported here.

CASE 1. C. H. Presbyterian Hospital, Unit History No. 323125. A man 63 years of age, a private patient of Dr. F. B. St. John, came to the hospital in December, 1931, with a 6 month history of increasing difficulty in bowel movement. It was found that he had a carcinoma of the sigmoid colon with considerable dilatation of the gut above it. A preliminary cecostomy was done with a tube held in the cecal wall by two pursestring sutures. Two sutures were taken in the external oblique aponeurosis and two in the skin. On the eighth day the upper angle of the cecostomy incision was found to be red and swollen; the skin sutures were removed. On the twelfth day the upper margin of the wound at the outer end became purplish in color around the outer suture hole while the inner end of the wound began to show evidences of early involvement. The whole area became red, swollen and exquisitely tender. Within a few days the margin of the wound and the area around the suture hole became frankly gangrenous and the purplish zone and red zone gradually spread outward. Just at that time an almost fatal coronary episode diverted attention from the wound. The process continued to spread slowly in two directions from the upper and lower ends of the wound. On the twenty-seventh day the writer was asked to see the patient, at which time the lesion had the fol-

lowing appearance (see Fig. 1). There was a large involved area in the right lower quadrant which was oval in shape and oblique in direction corresponding to the incision made for the cecostomy. At the inner and outer ends there were two areas of gangrene which were separated from one another: a circular one at the lower end and an oval one at the upper. The lower and outer margin of the wound was slightly rolled in and the fecal fistula, about 1 centimeter in diameter near the center of the wound, was surrounded by pale granulations. In the two gangrenous areas the dead skin was firmly adherent. On the lower lesion it measured about 2 to 3 centimeters in diameter and on the upper lesion about 2 by 6 centimeters. The outer margin of gangrene was scalloped at the line of demarcation and the living skin for a distance of 2 to 3 millimeters was dark purple. Beyond that for a distance varying from 5 to 10 millimeters there was a grayish purplish zone which stood up from the skin surface like a plateau. Beyond that the skin was very red for a distance varying from 2 centimeters below to 5 centimeters above. The outer margin of redness was not clearly defined but faded off rather quickly into normal skin.

On the next day the whole lesion was excised with complete cessation of pain. The gangrenous process did not recur and 5 days later it was possible to proceed with a Miles operation for the sigmoid carcinoma in the left lower quadrant. The denuded area on the right side rapidly granulated over and was covered with small skin grafts 3 weeks after excision.

When the lesion was removed it was taken to the laboratory and careful cultures were made of the subcutaneous tissue in the periphery of the lesion, after the skin surface was painted with 7 per cent iodine and the deep surface was seared. In three different places the microaerophilic non-haemolytic streptococcus (*Streptococcus evolutus* of Prevot) was found in pure culture by anaerobic methods. Cultures from the gangrenous margin yielded a multiplicity of fecal organisms and the plates were overgrown with *Bacillus proteus* so that further identification was impossible. A careful microscopic search for amebae on the surface of the lesion and in the tissues revealed nothing resembling those organisms. Staphylococci and streptococci were abundant in the tissues at the gangrenous margin and streptococci were found in smaller numbers out toward the periphery of the lesion.

CASE 2. A private patient of Dr. Roswell L. Schmitt, Morristown, New York, a single American school teacher of 61 years was admitted to the Horton Memorial Hospital, Morristown, New York, on August 11, 1931 as Patient No. 4506 with a diagnosis of acute appendicitis with abscess. Operation was performed immediately after admission. A right rectus incision was used. The appendix was found extending downward over the brim of the pelvis and buried in a mass of adhesions including loops of the small intestine and possibly tube and ovary. On separating these adhesions, thick green

Fig. 2. Case 2. Note the lower right rectus incision and the large area of granulations surrounded by a large horse-shoe shaped zone of gangrene extending almost to the costal margin. Beyond the gangrene there is a raised purple zone merging into a brilliant red zone which fades off into normal skin. On the surface of the granulation tissue there are three small areas of regenerating epithelium which are not clearly shown.

pus was liberated and a necrotic appendix was released and removed. Two cigarette drains were placed down to the abscess. Dermal sutures were used for the skin.

The wound drained copiously. On the fifth day after operation the patient complained of soreness in the wound. The discharge seemed to be fecal. The skin edges became inflamed so the skin sutures were removed and the wound edges were separated. The inflammation increased and the wound margins gradually developed a carbuncular appearance. Dressings became extremely painful the edges of the wound then gradually became gangrenous and a line of demarcation appeared. Around the area of gangrene was a purple zone and outside of that the skin was very red for a distance of $\frac{1}{2}$ to 1 inch. These zones gradually spread outward and the inner margin of the gangrenous skin liquefied leaving a floor of granulation tissue. During the next 65 days, in spite of all kinds of local applications and general measures to build up the patient's resistance the lesion continued slowly to progress. By the seventh postoperative day the gangrene had extended to include most of the skin of the abdominal wall. The writer was then asked to see the patient. At that time the lesion presented the typical appearance in the spreading margin but the red and purple zones were narrower than in Case 1. The gangrenous zone varied in width from 0.5 to 4 centimeters. There was a large area of granulation tissue with three islands of regenerating epithelium (Fig. 2). Radical excision was advised and this was accomplished with a scalpel. The line of excision was carried well outside of the red zone. Cultures, which were made in the operating room from the line of incision on semi-solid 1 per cent dextrose veal agar showed a pure growth of non hemolytic streptococci

Fig. 3. Case 3. Note the upper right rectus incision which has healed and the lateral stab wound used for drainage. The area of gangrene is bilobed corresponding to the retention sutures of the second operation. The zone of gangrene is scalloped at the outer margin where it is firmly attached to the raised purple zone. Beyond that there is a wide zone of redness extending up over the ribs margin and across the scar of the first operation. The granulation tissue is narrow with the drainage opening at the upper end.

Cultures made from the necrotic edge of tissue showed streptococci, staphylococci and gram negative bacilli on several different media (blood agar, plain agar, dextrose agar and plain and dextrose broth). These organisms were not further identified. The specimen was taken to New York and 4 hours later cultures were made from various parts of the lesion. All of the cultures were overgrown with *Bacillus proteus* but by differential heating this organism was killed and the micro-aerophilic streptococcus was recovered. The histologic examination of the tissues revealed staphylococci and streptococci in the tissues but no moribund were found after careful search. Following excision dakinized dressings were used for 6 weeks at which time the wound was clean. Thiersch grafts were then applied and the patient made a complete recovery.

CASE 3. A private patient of Dr. John H. Carlisle, Passaic, New Jersey. M. S. aged 57 years was admitted to the Passaic General Hospital, Passaic, New Jersey as Case No. 75668 on October 30, 1932. For 12 years the patient had suffered from duodenal ulcer. On two occasions X rays were taken which showed a definite ulcer in the first part of the duodenum. On the evening of October 29, he had a supper of oyster stew and went to bed fairly early

feeling quite well. About midnight the ulcer perforated. He was not seen until the following morning and operation was performed at 1 p.m., 13 hours after the perforation.

A perforation was found on the anterior surface of the first part of the duodenum. A simple suture was done and reinforced with a flap of fat so that the closure was thought to be quite satisfactory. The wound was closed but drainage was provided through a stab wound on the right. This was thought necessary because the gall bladder and structures in Morrison's pouch were covered with fibrinoplastic exudate. Cultures were not taken. After operation he persisted in running a low temperature. On the twenty-seventh day it was evident that he had a subphrenic abscess and an intermuscular incision was made under the right ribs. When the peritoneum was opened, pus was immediately encountered. Culture from this pus yielded no growth with aerobic technique. No anaerobic cultures were made. No liver abscess could be made out. Two cigarette drains were placed in the abscess and the wound was closed in layers around the drains with two retention sutures for the skin. Following the drainage of the abscess, the temperature fell somewhat but continued around 100 to 101 degrees in the afternoons. There was a profuse drainage of pus. On the fifth day the wound was swollen and showed marked infection. The drains and the skin sutures were removed. The next day the old stab wound scar broke down discharging pus. On the eighth day there was considerable necrosis of the wound margins, most marked where the tension sutures had been placed. The patient complained of a great deal of burning in the wound and in the abdominal wall extending back along the course of the spinal nerves. The necrotic margins were cut away and various antiseptics were used but the infection continued to spread. On the fourteenth day the infection began to spread more rapidly toward the flank. A diagnosis of symbiotic gangrene was then made and the writer was called to see the patient. The lesion at this time appeared as follows: The upper right rectus incision was well healed. In the right upper quadrant there was an area showing a striking similarity to the lesion in Case 1 (see Fig. 3). There was a zone of gangrenous skin from 1 to 3 centimeters in width, a raised purple zone outside of it from 7 to 10 millimeters in diameter and outside of that a brilliant red zone from 1 to 3 centimeters in width which gradually faded off into normal skin. There was a narrow strip of granulation tissue on the floor of the wound and a sinus opening near the center. Below this lesion there was a small scar representing the original drainage tract. A wide excision was advised and operation was performed within an hour. The line of excision was carried about 3 centimeters beyond the reddened area. The skin and superficial fat were excised down to the fascia. The wound was dressed with fine meshed gauze wet with Dakin's solution. On the sixth day the defect was covered with pinch skin grafts and rapidly epithelialized.

Before operation cultures were made from the pus at the mouth of the drainage tract and from the gangrenous skin. At the time of operation bits of subcutaneous fat in the line of excision were cultured. After operation the specimen was taken to New York and within an hour of the time of its removal the skin was painted with metaphen and the deep surface was seared and further cultures were made of the subcutaneous fat at varying distances from the margin of the specimen toward the gangrenous zone approaching it from the deep surface as well as through the skin. Half of these cultures were incubated at 37.5 degrees C. aerobically and the other half in an anaerobic jar. From the drainage tract and from the slough the micro-aerophilic non-hemolytic streptococcus greatly predominated but was associated with hemolytic and non hemolytic *Staphylococcus aureus* and *Staphylococcus albus*. From the subcutaneous fat away from the zone of gangrene the micro-aerophilic non hemolytic streptococcus was found in pure culture in 3 of 5 taken from the skin side and in 4 of 5 taken from the deep surface. In 2 of the 5 from the skin side, it was associated with aerobic spore forming rods, evidently skin contaminating organisms which resisted the iodine. In the fifth culture from the deep surface the streptococcus was associated with a *Staphylococcus albus*. The cultures from the line of excision in this case yielded no growth. A careful study of the three taken for pathological examination failed to reveal anything resembling amebae.

All 3 of these cases yielded the microphilic streptococcus in pure culture at the periphery of the lesion. Two of them were contaminated by a bacillus of the proteus group in the area of gangrene which made difficult the demonstration of other organisms although staphylococci were seen in the tissue sections and in the mixed culture. The third case did not yield a bacillus of the proteus group but yielded *Staphylococcus aureus* and *albus* in the slough. We believe that these 3 cases amply confirm the conclusions reached after study of the 2 cases previously reported, namely: that the essential organism in this lesion is the micro-aerophilic non hemolytic *Streptococcus evolutus* (Prévot) but that the gangrene which is characteristic of the infection occurs only when this organism is in symbiosis with some other species—generally some variety of staphylococcus.

GANGRENOUS IMPETIGO (ECHTHYMA)

For a good many years reports have appeared in the literature describing a chronic gangrenous disease of the skin appearing in

undernourished individuals both young and old who were generally in a low state of nutrition and were frequently suffering from recurrent attacks of dysentery. It has been given many names by the dermatologists, among them *echthyma*, *pyoderma gangrenosum*, *impetigo gangrenosum*, *dermatitis gangrenosa* etc. etc. Recently such cases have been described in the periodical literature by Hartzell, Kitchmann and Kreibich, Wende and Bentz, Hu, Brunsting, Goeckerman and O'Leary, Morrissey and Reynolds, McCarthy and Fields and others. Most of the textbooks, Unna, Stelwagon, Sutton, MacLeod, Hazen and Andrews have stated that this disease is simply a severer and deeper form of impetigo, but Shamberg was of the opinion that they were distinct.

Symptomatology. The lesions are usually multiple and show various stages of development, one lesion following another in rather rapid succession. They occur most frequently on the scalp, face and abdomen but may be found on any part of the body. They generally start as small vesicles surrounded by a red zone. The center then becomes dark and gangrenous and depressed. The lesion increases in size slightly and occasionally two or three neighboring lesions may coalesce but even the coalesced lesions seldom measure more than 1 or 2 centimeters in diameter. The disease is contagious and frequently occurs in several members of a family at the same time. Likewise the patient inoculates other areas of his body. As new lesions develop the old ones frequently dry, the necrotic skin comes off as a scab and a scar is left behind. The larger and deeper lesions, however, may persist for a long time. The gangrenous center then separates at the margin leaving a ring of depressed ulceration from the center of which the gangrenous plaque stands up like a button. If this separates from its base a clean ulcer is left which slowly heals. This condition may last for months or years with exacerbations and remissions and frequently a crop of small fresh gangrenous lesions may develop after a recurrence of diarrhea or colitis.

Etiology. The cause of these lesions has been variously explained by different authors. Most dermatologists consider this condition to

be a serious form of impetigo. The onset of the lesion with vesiculation makes this seem plausible. The organism generally attributed to be the cause of impetigo is the hemolytic streptococcus. Some authors have attributed *echthyma* to the action of *Bacillus pyocyaneus*, others to staphylococci and still others to other streptococci. One of these cases died with a general sepsis in which three different organisms were successively found in the blood (42). This finding leads to some uncertainty with regard to their rôle in the etiology of the disease. Leloir in 1880 found both staphylococci and streptococci in 5 of these cases but he was unable to produce the disease in animals with these organisms in pure culture and thought that there might be some other etiological agent. Brunsting, Goeckerman and O'Leary regularly found a hemolytic streptococcus and a staphylococcus in the lesions and following the suggestion which the writer made with regard to progressive postoperative gangrene they attributed the disease to a synergistic action of these organisms. With these two organisms in combination they were able to produce similar lesions in animals. These authors did not explain the association of this disease with colitis or dysentery. Fox believed that if cultures are made early while the lesions are still vesicular the hemolytic streptococcus will be found invariably in pure culture but later when the gangrene develops staphylococci are present also. He did not suggest the possibility of synergism between the two. In studying this disease anaerobic cultures have rarely been made.

Treatment. Hartzell's case, although it resembled the others in its onset, differed from them in that excision of the lesions was the only method which effected their disappearance. He said that when the lesions were thoroughly excised together with a considerable margin of sound skin, the wound thus made, rapidly healed. If, however, all of the infected tissues were not removed, as happened frequently the wound became a steadily enlarging gangrenous ulcer with firm elevated borders like those which resulted from untreated lesions. There was no bacteriological study of Hartzell's case. Hartzell has been the only one to advocate complete excision of

these lesions, and his case may have been different from the others for in almost all of the other cases reported there was spontaneous healing following the separation of the necrotic tissue. Various and sundry local medications have been applied by different authors most of which had some measure of success. In a good many cases while the individual lesion healed recurrences dragged on for months or years. Most of the writers however believe that the majority of these cases will recover if general nutritional measures are instituted and if the usual methods of treating impetigo are continued industriously.

FUSOSPIROCHETAL INFECTION OF THE SKIN

A third type of chronic gangrene is represented by the foul infections developing in wounds made by human bites or in wounds which have been contaminated by mouth secretions. Leeuwenhoek was probably the first to observe the spirochætae, the spirilla and the fusiform bacilli which frequent the human mouth but the classic work of Miller in 1890 offered the first comprehensive description of the mouth organisms. In 1894 Plaut (7) suggested the causative significance of the spirochæta and spirilla in certain of the non-diphtheritic infections of the throat and 4 years later Vincent stressed the rôle of the fusiform bacilli without recognizing the prior observations of Plaut. In 1905 Plaut and Vincent debated the question. In 1896 Vincent (91) had observed spirochætae in cases of hospital gangrene and believed them to be responsible for it. Eggers, in 1915 in the course of a morphological study of over 2,000 smears from chronic skin ulcers in patients in various parts of China, found spirochætae in about 10 per cent. They were frequently found in the lesions commonly known as "tropical sore." Plaut (74) later found the combination of fusiform bacilli and spirochætae in two "non-ulcer-like" lesions of the skin.

Stiles and Hassall, in their classification of the protozoa reported for man state that the spirochætae which are pathogenic for man are limited to the *Treponema* and *Leptospira* groups. Smith, in his recent book on fusospirochætal diseases lists four species of

spirochætae and three types of fusiform bacilli which occur in the human mouth and which have been found in human infections.

Hospital gangrene practically disappeared when surgeons began to have a little understanding of bacterial contagion and infection. It is almost certain therefore that it was an infectious type of gangrene. Whether or not it was due to a specific organism or to a specific combination of organisms not including the spirochætae or to the fuso-spirochætal group as Vincent claimed may never be determined. Warren believed that the term included a number of different acute and subacute forms of infectious gangrene. The writer cannot add anything to the solution of this problem from personal experience but agrees with Warren after studying a number of the reports which appeared in the medical literature following the Civil War and later.

In recent years gangrene of the skin and subcutaneous tissues, in which the fusospirochætal organisms play a part has generally occurred following the implantation of mouth organisms into the tissues by human bites. Flick has recently reviewed the literature and added 5 cases to the ones which had been reported previously by Hultgen, Peters, Hennesey, Madras, and Fletcher, Pilot and Meyer, Folger and Cottrell, Bower and Lang.

A human bite invariably contaminates the wound with a mixture of organisms. Bates says that the police surgeons fear the severity of these infections more than any other type of infected wound. Usually gangrene does not develop in these cases unless there is a mixture of organisms which includes non-hemolytic streptococci, fusiform bacilli and spirochætae. Although spirochætae are never found alone in these infections the worst cases are certainly those in which spirochætae are present. The infection almost always occurs either when a human being voluntarily bites another or strikes a blow with the hand which is cut by the teeth of the intended victim. The wound is usually a lacerated wound of considerable depth, but cases have been reported in which the injury was very superficial and one case followed the picking of a superficial blister with a pen knife with which the patient was accustomed to pick his teeth. It is surprising

that more wicked infections do not develop in wounds which have been sucked, for this is a common practice. It is probable that organisms are not planted in the depths by this procedure.

Symptomatology. There is usually some evidence of inflammation within the first 2 or 3 days after receipt of the injury and this steadily progresses. The exudate becomes foul, the margins of the wound are shaggy, bleed easily, and take on a dark grey-green appearance. The infection may spread fairly rapidly into the neighboring bones and joints. It burrows down into the deep spaces and may work up again toward the surface and break out at some distance from the original wound. Thus multiple sinuses are produced or if incisions are made in various places the wounds remain open and continue to discharge the foul smelling exudate. Unless the proper treatment is instituted these infections go on steadily for weeks or months with a progressive destruction not only of the skin and subcutaneous tissue but of the deeper structures.

Etiology. If smears are made from the foul exudate countless organisms are seen among them streptococci fusiform bacilli and spirochaetae—the latter are better seen with the darkfield illumination. These organisms will develop only under anaerobic conditions and are grown best in or on special media. A great many serious human bites occur in which only streptococci and staphylococci are found but usually in these cases although infection is severe and the general symptoms marked, there is no gangrene of the tissues. Although hemolytic streptococcus gangrene might develop after a human bite such a case has not come into the experience of the writer. If gangrene is present, either the fusiform bacilli or the spirochaetae are usually to be found and the severer cases harbor both of these organisms. There has been some debate among the investigators of these Plaut-Vincent infections as to whether the fusiform bacilli and spirochaetae are two different organisms growing in symbiosis or represent two different stages of the same organism. Tunncliffe is of the opinion that spirochaetae develop from the fusiform bacilli. She reports that she has actually seen this development taking

place. However, this has not been confirmed by other writers who claim that although twisted forms of the fusiform bacilli do appear in old cultures, the spirochaetae which occur in these infections represent a different species and that it is a true symbiotic infection. Knorr goes further in stating that he has never seen a case of infection with either fusiform bacilli or the spirochaetae without streptococci being present also. He believes these infections are symbiotic in nature and that the streptococcus plays a necessary and an important rôle.

Treatment. Bates who has had considerable experience with infections of this kind now treats wounds caused by human teeth with radical excision as soon as they come to him. This he believes is an important prophylactic measure. When the infection has already gained a foot hold most authors have found that any temporizing measure is unsuccessful and they advocate fairly radical surgery which generally involves amputation of a finger or hand. The presence of spirochaetae has suggested the treatment of these infections with spirochaetocidal chemical substances and although arsphenamine has frequently been used without success, better results have been obtained with neo-arsphenamine. This should certainly be tried before any radical surgical procedures are used, but temporizing measures should not be continued if there is no very definite improvement. Otherwise extensive destruction of important structures may take place.

AMEBIC INFECTION OF THE SKIN

The ulcerative lesions of the intestine in which *Endamoeba histolytica* is found are well known. The most frequent parenteral site for the activity of this protozoön is in the liver and the lesion within that organ may be a single abscess or multiple abscesses. It is of interest that all efforts made toward artificial cultivation of amebae in the absence of other organisms has failed. Likewise in the lesions within the body, the amebae are almost always associated with some of the intestinal bacterial species (in symbiosis). In the early stages, the liver abscesses frequently yield these associated organisms on culture and the presence

of the amoeba is not suspected. In later stages after the infection has become established, cultures may fail to reveal bacterial organisms but scrapings of the abscess wall will yield living amoebae. It seems to be possible, therefore, for the amoeba alone to maintain a lesion in the human body although in many of these cases there may be anaerobic organisms present which have not been revealed by culture.

Amoebic infection of the skin has been described by a number of authors practicing in regions in which amoebic disease is common. In most of the cases which have been reported the involvement of the skin has been secondary to the spontaneous or operative drainage of a liver abscess. Such cases have been described by Heimberger, Nasse, Daborn and Heymann, Heymann and Ricou, Gauducheau, Carmini, Cheng, Engman Jr and Henry, Meloney and others. A few cases of skin infection have followed some operative procedure on the large gut, e.g. Cole and Heideman, Marwitz and Van Steenis. By two observers, Maxwell and van Hoof, fistulas about the anus have been attributed to the action of amoebae.

Gangrenous lesions of the skin attributed to amoebae which seemed to arise without any direct connection with an internal focus of the disease have been listed only twice in the recent literature. In 1919, Engman, Sr and Heithaus reported a case which came under their observation and they fully described the course of the infection. In this case the disease developed secondarily in several of the lesions of impetigo from which the patient had been suffering. The amoeba which they described was assumed to be but was not definitely classified as *Endamoeba histolytica*. They included in their report 2 other cases which may belong to this group but the evidence is not perfectly clear. Similarly in a case reported by Hansen and Stark the findings are not absolutely convincing because the organisms were not found in the lesions although they were said to be present in the stools.

Symptomatology. In the cases which develop a gangrenous lesion of the skin secondary to the drainage of a deeper focus, there is always a period of days or weeks during which there

is no specific change in the wound. The drainage tract becomes red, swollen, and painful in a manner similar to that in many drained wounds. Then the edges become indurated, everted and raised above the surrounding skin which takes on a dark brown color with hyperpigmentation. As the necrosis spreads, the center of the lesion remains as an ulcerated surface covered with dark granulations having a color resembling that of raw beef which has been exposed to the air for some time" (Heimberger). The surface is covered with foul smelling exudate of thick brownish blood tinged pus with shreds of necrotic tissue in it. Usually the chief involvement is in the skin and subcutaneous tissue but the muscle may be involved in which case the whole wound becomes necrotic to a considerable depth, as in Engman Jr and Meloney's second case. In amoebic lesions which have no connection with a deep focus, Engman and Heithaus say that the infection with amoebae apparently must be preceded by an established infection with other organisms. This at once suggests the possibility of a symbiotic rather than a specific action. In such a case the infection remains relatively superficial. The spread seems to be in the cutis while the epidermis is involved secondarily and gives way. Glairy pus in small droplets may be expressed from the margin of the ulceration. This is said to be quite characteristic of the infection. If the proper treatment is not instituted the lesion continues to spread fairly rapidly in all directions until large areas are involved and the patient finally succumbs either to the involvement of a vital organ or to an intercurrent infection.

Etiology. In none of the cases, reviewed by the writer which have been attributed to amoebae, have careful anaerobic as well as aerobic bacteriological studies been made. The bacterial factor either alone or in symbiosis with the amoeba may not have been given the attention which it deserves. It seems to the writer that one or all of the following conditions should obtain before it can be fairly stated that amoebae are participating actively in any infection: (1) There should be histological evidence of the invasion of the tissues by the amoeba or (2) they should be

found either by smear or culture in the advancing margin of the lesion, or (3) the lesion should respond to emetin treatment recognized as adequate for amoebic disease. The writer believes that the mere presence of amoeba on the surface of the lesion or in the exudate is no more evidence of their participation in the infection than the presence of *Bacillus coli*, *Bacillus welchii*, *Bacillus proteus*, or any of the other intestinal organisms is evidence of their activity in the tissues about a faecal fistula. In most of the cases in which amoebae have been observed there has been no accurate determination of the type of amoeba but in those cases having a direct connection with amoebic lesion of the liver or gut it is frequently assumed that the organism is *Endamoeba histolytica*. In the case of Heimberger and in the second case reported by Engman Jr and Henry Meloney there seems to be little doubt that *Endamoeba histolytica* was present and played an important rôle in the infection. It is of particular interest to note that in Engman and Heithaus's case, bacterial cultures yielded no growth aerobically. After such a long exposure to contamination it is surprising that there were not secondary contaminants capable of growth even if the organisms responsible for the impetigo had disappeared. The spectacular response both generally and locally to the emetin treatment in this case as well as in Heimberger's case is strong evidence in favor of the importance of the amoebae in these infections. In the second case of Engman, Jr and Henry Meloney the invasion by the amoebae of the whole thickness of the abdominal wall including the muscle is a strong argument in favor of the activity of the amoeba in that case, although there was little response to emetin. The fatal outcome may have been due either to the extent of the amoebic lesion in the liver or the virulence of the associated hæmolytic streptococcus and *Staphylococcus aureus* in a patient with diabetes. In the first case presented by these authors although the organism found was almost certainly *Endamoeba histolytica*, the evidence is not so clear that the amoeba played an important rôle. No cultural studies were made of this lesion so that the factor of bacterial synergism could

not be weighed or measured. The amoebae were found in the pus and on the surface of the wound but not in the depths of the tissue nor were they found in the apparently healing ulcer in the gut. It may have been a surface contamination. On the other hand the temporarily favorable response to emetin may indicate that the amoeba played a partial rôle in the production of the lesion. In the case reported by Cole and Heideman there is still less evidence that the amoeba, which was found in the pus but was not classified as a factor in the infection. The organism was present in the exudate but not in the tissues. There was little if any response to emetin treatment even though the pathology seemed to be localized in the skin lesion. The disease was finally controlled only by a wide cautery excision such as is required in the bacterial synergistic gangrene. No anaerobic cultural studies were made in this case but the onset and the clinical course were typical of the bacterial synergistic gangrene and similar to the 5 cases of that type mentioned previously in lesions of which no amoebae were found after careful search by three parasitologists.

Treatment. In all cases of amoebic abscess of the liver, the possibility of skin necrosis after drainage must be kept in mind and precautions taken to avoid it. An attempt should be made to protect the skin wound at the time of operation. A two stage procedure might increase wound resistance to the infection. If a one stage operation is performed there should be complete relaxation of the wound with no attempt to close the skin and subcutaneous tissues by suture. If pathogenic amoebae have been found, emetin hydrochloride should be given intravenously. If this medication fails and the disease is localized to the surface lesion it should be widely excised. In all of these cases inasmuch as the bacterial symbionts always play a rôle of greater or lesser importance, a careful bacteriological study of the lesion should be made before operation and cultures taken from various portions of specimen after excision if that procedure be necessary.

DIFFERENTIAL DIAGNOSIS

The differentiation between the groups of chronic infectious gangrene is difficult, particu-

TABLE II.—DIFFERENTIATION OF CHRONIC CASES

Name	Etiology	Symptomatology	Pathology	Treatment
Postoperative progressive bacterial synergistic gangrene	Esenteral organisms micro-aerophilic non-hemolytic streptococcus (<i>S. erythrae</i>) in the spreading periphery of the lesion, associated with staphylococcus in the zone of gangrene.	Usually follows drainage of peritoneal abscess, lung abscess, or chronic empyema. Wound margins or retention scabs take after one or two weeks form a circumscribed appearance. Usually differentiated into three skin zones, outer bright red, middle dusky purple, and inner gangrenous with central area of granulation tissue. Excreting pus.	Destruction of epidermis and upper layers of dermis occasionally leaving some deep remnants of epithelium which may later grow. Under gangrene, heavy polymorphonuclear exudation. Under purple zone, leucorrhea. Under red zone, hyperemia. Many staphylococci and streptococci under gangrene. Scattered streptococci in the periphery.	Extensive excision of the whole mass well beyond the red zone of advance, either with the electric cautery-knife or with the scalpel. Skin grafting.
Gangrenous mycetoz (actinomyces)	Esenteral organisms hemolytic streptococcus and hemolytic staphylococcus	Usually occurs in debilitated persons especially those suffering from chronic dysentery. Lesions are usually multiple and may coalesce but are seldom large. Start as vesicles going on rapidly to pustules and gangrene.	Usually superficial destruction of tissue with drying of the gangrenous skin, scab formation, and separation. Moderate polymorphonuclear exudation. Local masses of staphylococci and streptococci.	Removal of crusts. Intravene local application of concentrated mercury and iodine. General nutritional treatment.
Favopurulent gangrene	Esenteral organisms fusiform bacilli, spirilla, and sporobacteria usually associated with non-hemolytic streptococci	Usually occurs in wound contaminated with mouth secretions, a lesion here. Early induration with gradual development of necrosis of wound edges with protrusion to bones and joints.	Extensive sloughing of superficial and deep tissue with multiple scab formation. Organisms profuse in exudate and in the necrotic tissue.	Intravene administration of neoarsphenamine. Radical amputation if necessary.
Abscess infection gangrene	Esenteral organisms fusiform bacilli, spirilla, and sporobacteria associated with non-hemolytic streptococci, staphylococci, and local organisms.	Usually follows the drainage of an abscess abscess of the liver. Margins raised and everted. Granulations have appearance of raw beef covered with streaks of necrotic material. Gray put excreting from margin.	Extensive destruction of dermis with undermining and secondary destruction of epidermis. Polymorphonuclear exudation. Amoebae and bacilli present even in the strata and in the tissue.	Extensive administration of sodium hydrochloride intravenously. Radical resection of the lesion if disease is limited to the skin and medication fails.

larly between the bacterial synergistic and the amoebic groups both of which usually follow an operative procedure. In the bacterial synergistic group there is no history of amoebic infection or evidence of deep amoebic lesion no amoebae are found either in the stools or in the exudate from the lesion or in the tissues and there is no response to emetin treatment. In the amoebic cases there is frequently a history of previous amoebic dysentery or a frank deep amoebic lesion. Amoebae are frequently found in the stools as well as in the exudate from the wound and in the tissues and the lesions may respond promptly often surprisingly to emetin treatment. In bacterial synergistic gangrene the lesion is extensive but superficial and develops slowly. It does not invade the muscle and the base of the ulcerated center is composed of active granulations which frequently reveal isolated islands of regenerating epithelium. In the amoebic infections the lesion is usually deeper. It develops more rapidly and it may involve the muscle. The granulations have a raw beef appearance and islands of regenerating epithelium are rare. Pressure on the margins produces glairy

pus in which the amoebae may be found. All of the cases of postoperative progressive bacterial synergistic gangrene which have been examined at the time of excision have yielded a micro-aerophilic non-hemolytic streptococcus in pure culture in the spreading periphery of the lesion while cultures in the zone of gangrene have revealed this organism in association with others. As far as the writer is aware the advancing margin of the amoebic lesions has never been examined bacteriologically but the exudate almost invariably yields beside the amoebae a combination of organisms which may contribute toward the severity of the infection. Until complete bacteriological studies have been made in amoebic cases there cannot be any satisfactory pathological or bacteriological differentiation between these two groups.

Gangrenous impetigo and fusio-spirochetal gangrene of the skin are more easily differentiated. The former almost always occurs in individuals suffering from some debilitating disease especially a chronic dysentery. The lesions are multiple and follow one another with great persistence over a period of months

or years. Fusospirochætal gangrene almost always develops in a wound deeply contaminated with human mouth secretions such as a human bite. Gangrenous impetigo usually starts as a vesicle which becomes gangrenous in a few days but does not spread widely or deeply. In fusospirochætal infection, the lesion progresses steadily and penetrates deeply to muscle tendon joint and bone with a massive destruction of tissue. Multiple sinuses are prone to develop and persist. From the lesions of gangrenous impetigo the hæmolytic streptococcus and staphylococcus may both be cultured. From the Plaut Vincent infections fusiform bacilli spirilla, and spirochæte may be found on smear or culture or with the dark field illumination but there is usually some type of streptococcus generally non hæmolytic, also present.

The differentiation of the types of chronic infectious gangrene may be conveniently summarized in chart form (Table II)

SUMMARY AND CONCLUSIONS

In this paper we have attempted to differentiate clinically as well as bacteriologically, the various types of gangrene of the skin and subcutaneous tissue due to the invasion of microorganisms. They may be conveniently divided into acute and chronic forms.

The acute types are essentially diseases caused by single bacterial species although their severity may be augmented by associated organisms. They comprise (a) gas gangrene and (b) hæmolytic streptococcus gangrene. Their differentiation from one another and from erysipelas is summarized in Table I.

The chronic types are essentially diseases due to a mixture of organisms growing in symbiosis. These organisms in pure culture are either innocuous or produce lesions which are not gangrenous. They comprise (a) progressive bacterial synergistic gangrene (b) gangrenous impetigo (c) fusospirochætal gangrene and (d) amœbic infection of the skin. Their differentiation is summarized in Table II.

The early differentiation of these infectious forms of gangrene is essential in order that the proper treatment may be instituted early. For in that way extensive loss of tissue may be

prevented the duration of illness may be shortened and lives may be saved.

Three additional cases of progressive postoperative bacterial synergistic gangrene are herein reported.

REGENERATIVE CAPACITY OF THE EXTRAHEPATIC BILIARY TRACTS

CLINICAL AND EXPERIMENTAL STUDY

GEORGE HALPERIN, M.D., M.S., F.A.C.S., Chicago

From the Department of Surgery at Northwestern University

OPERATIVE procedures required for the repair or reconstruction of the extrahepatic bile tracts present a number of difficult problems and generally speaking constitute a difficult and ungrateful chapter in surgery. Cicatricial stenosis and partial or complete obliteration of the common bile duct as well as of the hepatic duct may be caused by the following conditions:

1. Congenital anomaly such as diverticulum of the common bile duct
2. Benign and malignant neoplasms involving the common bile duct, the head of the pancreas papilla of Vater, the gall bladder or the cystic duct
3. Inflammatory conditions (a) decubitus ulcer in the common duct caused by a stone (b) inflammatory induration of the lower end of the common duct, result of a large callous ulcer of duodenum (c) acute or chronic indurative pancreatitis
4. Postoperative strictures.

The first three groups are relatively rare. The greatest number of cases calling for repair or reconstruction is furnished by the postoperative group. The most frequent cause of postoperative stricture of the choledochus or the common hepatic duct is a technical error committed in a course of a cholecystectomy and passed unnoticed at the time. Occasionally stenosis has taken place after a supra duodenal choledochotomy done for exploration and removal of stones, regardless of whether the incision was drained or closed primarily. The use of a T tube especially if too early removed has been a not infrequent cause.

There is a group of cases in which stenosis developed in spite of faultless technique and in the absence of complications. Here belong cases of phlegmonous inflammation of the extrahepatic bile ducts in which the suppurative process ordinarily limited to the gall bladder extended to and involved the com-

mon bile duct. The stenosed duct in such an instance is analogous to a shrunken gall bladder the result of a purulent cholecystitis. It is noteworthy that such cases have been found only after an operative procedure and never primarily.

Much more difficult is the explanation of cases, fortunately rare, in which stenosis occurred after a meticulously carried out operation and in the absence of inflammatory adhesions. A possible explanation may be found in a constitutional predisposition to connective tissue hyperplasia. The use of a drain may be responsible in some instances for an excessive connective tissue reaction. As is well known, injury to the common or the hepatic duct in the course of a cholecystectomy has occurred in the hands of master surgeons and need not be charged to a lack of skill or care in the performance of the operation. Correct anatomical orientation is not always possible. Variations in the normal arrangement of bile ducts and blood vessels particularly in the presence of inflammatory conditions, make the recognition of the essential structures very difficult, at times impossible. Ruge in an anatomical study, made at the suggestion of Koerte examined 43 human cadavers and found that the cystic duct joined the common hepatic in one of three ways: (1) In 35 per cent of the cases at a sharp angle. (2) In 30 per cent the cystic ran parallel with the common hepatic for a variable distance before joining the latter. The two may be so closely bound as to make their separation difficult. It is this type that Delbet characterized as canal double hepato-kystique. (3) In 45 per cent of the cases the cystic duct ran a spiral course and joined the hepatic on its left side.

The subject of anomalies was further studied with essentially similar results by Kunze, Descomps, Rio-Branco, Eisendrath, Behrend, and others.

The operative injury is most frequently the result of inclusion of a part or of the entire thickness of the common bile duct or of the hepatic in the grasp of the forceps or ligature intended for the cystic alone. Next in frequency is the attempt to grasp blindly a severed, retracted, and spurting cystic artery. The injury, if recognized at the time of operation should be repaired immediately. Its later repair in a jaundiced patient with a tendency to cholamic bleeding, and in the presence of baffling adhesions and altered anatomical relations becomes an infinitely more difficult, if not an altogether hopeless task.

CLINICAL EVIDENCE REGARDING THE REGENERATIVE CAPACITY OF THE EXTRAHEPATIC BILE DUCTS

It is a well established fact that partial defects of the choledochus especially if they be longitudinal, heal spontaneously and only rarely display a tendency to scar contraction. The difficult problem is presented by cases in which so much of the duct is stenosed or destroyed that an end-to-end anastomosis is impossible. If the gall bladder is available a short-circuiting operation of cholecystogastrostomy or cholecysto-enterostomy saves the situation. Most of the cases under consideration, however have had a previous cholecystectomy. Doyen as early as 1892, did the first choledochorrhaphy over a buried tube. Halsted attempted the same in 1900. Both operations resulted in failure. When the gap between the proximal stump and the duodenum or the stomach is not too great, and if the duodenum can be mobilized the problem is relatively simple the *direct anastomosis* between the hepatic or the common duct and the duodenum giving excellent results. The first hepaticoduodenostomy was performed by Hans Kehr in 1902 (33) and was described in his "Die Geübte Technik der Gallensteinoperationen." W J Mayo (46 47) reported a successful hepaticoduodenostomy in 1905. The case was again reported 10 years later by himself and 16 years later Balfour reported the patient as being in perfect health. In cases in which a direct end-to-end anastomosis of the severed duct is impossible because of the

extent destroyed, or because of inflammatory conditions, or adhesions which make mobilization of the duodenum impossible artificial reconstruction of the duct is the only alternative left. For these difficult cases three methods have been advanced.

- 1 Plastic operation utilizing pedunculated flaps carved from the gall bladder wall stomach wall duodenum or jejunum as well as the use of a transplanted vein fascia etc.

- 2 A two step operation consisting first of forming an external biliary fistula from the gall bladder cystic common, or the hepatic duct. This fistula is cored out at a second operation and is implanted into duodenum or stomach.

- 3 Bridging the gap between the two ends of a severed duct, or between the proximal stump of the duct and duodenum or stomach by means of a rubber tube.

Hans Kehr (33 34) was the first successfully to employ a seromuscular flap from the stomach in one case (in 1907) and from the gall bladder in another, to cover a defect in the common bile duct. Stubenrauch in 1906 successfully employed a flap carved from the stomach in one patient. His attempts to perform the same operation in dogs were not successful. The recent experiments of Schrager and Ivy with the flap method proved that this procedure was feasible at least in dogs, provided that a tube fashioned out of gastric mucosal layer only was used. Ivy (personal communication) doubts however, that such tubes can be made fairly long without endangering their blood supply and thereby compromising the end results. Furthermore all of their dogs developed a hepatitis. Attractive as all of these methods may appear in theory or in animal experimentation, their practical application in human beings is seldom possible.

Priority in the use of the method of fistula implantation undoubtedly belongs to Czerny as correctly pointed out by Horgan in a recent monograph. Successful results with the method have been reported by Stubenrauch in 1906, by Kausch in 1914, and more recently by Lahey and by Walters. Kausch reported a case which functioned normally $1\frac{3}{4}$ years later. It was his conviction, however that

REGENERATIVE CAPACITY OF THE EXTRAHEPATIC BILIARY TRACTS

CLINICAL AND EXPERIMENTAL STUDY

GEORGE HALPERIN M.D., M.S. F.A.C.S., CHICAGO

From the Department of Surgery of Northwestern University

OPERATIVE procedures required for the repair or reconstruction of the extrahepatic bile tracts present a number of difficult problems and generally speaking constitute a difficult and ungrateful chapter in surgery. Cicatricial stenosis and partial or complete obliteration of the common bile duct as well as of the hepatic duct may be caused by the following conditions:

1. Congenital anomaly such as diverticulum of the common bile duct
2. Benign and malignant neoplasms involving the common bile duct, the head of the pancreas, papilla of Vater, the gall bladder or the cystic duct
3. Inflammatory conditions (a) decubitus ulcer in the common duct caused by a stone, (b) inflammatory induration of the lower end of the common duct, result of a large, callous ulcer of duodenum (c) acute or chronic indurative pancreatitis
4. Postoperative strictures.

The first three groups are relatively rare. The greatest number of cases calling for repair or reconstruction is furnished by the postoperative group. The most frequent cause of postoperative stricture of the choledochus or the common hepatic duct is a technical error committed in a course of a cholecystectomy and passed unnoticed at the time. Occasionally stenosis has taken place after a supra-duodenal choledochotomy done for exploration and removal of stones regardless of whether the incision was drained or closed primarily. The use of a T tube especially if too early removed has been a not infrequent cause.

There is a group of cases in which stenosis developed in spite of faultless technique and in the absence of complications. Here belong cases of phlegmonous inflammation of the extrahepatic bile ducts in which the suppurative process ordinarily limited to the gall bladder extended to and involved the com-

mon bile duct. The stenosed duct in such an instance is analogous to a shrunken gall bladder the result of a purulent cholecystitis. It is noteworthy that such cases have been found only after an operative procedure and never primarily.

Much more difficult is the explanation of cases fortunately rare in which stenosis occurred after a meticulously carried out operation and in the absence of inflammatory adhesions. A possible explanation may be found in a constitutional predisposition to connective tissue hyperplasia. The use of a drain may be responsible in some instances for an excessive connective tissue reaction. As is well known injury to the common or the hepatic duct in the course of a cholecystectomy has occurred in the hands of master surgeons and need not be charged to a lack of skill or care in the performance of the operation. Correct anatomical orientation is not always possible. Variations in the normal arrangement of bile ducts and blood vessels, particularly in the presence of inflammatory conditions, make the recognition of the essential structures very difficult at times impossible. Ruge in an anatomical study made at the suggestion of Koerte examined 43 human cadavers and found that the cystic duct joined the common hepatic in one of three ways: (1) In 35 per cent of the cases at a sharp angle. (2) In 20 per cent the cystic ran parallel with the common hepatic for a variable distance before joining the latter. The two may be so closely bound as to make their separation difficult. It is this type that Delbet characterized as canal double hepato-kyrtique." (3) In 45 per cent of the cases the cystic duct ran a spiral course and joined the hepatic on its left side.

The subject of anomalies was further studied with essentially similar results by Kunze, Descomps, Rio-Branco, Eisendrath, Behrend and others.

Doberauer mentions one other case in the literature, that operated on by Kehr in 1905 and mentioned in his "Die Geuebte Technik der Gallensteinoperationen." In Kehr's case the gap amounting to 6 centimeters was bridged by a rubber tube sutured into the hepatic duct and introduced through a stab into the duodenum. The patient was well 2 years after the operation. In still another case reported by Liebold, Kehr approximated the posterior surfaces of the two ends with three sutures and then turned in a flap carved from the gall bladder to cover the defect in the anterior wall of the common duct.

Voelcker did not consider it safe to leave the catheter in. In his first case he solved the problem by leading the catheter out of the duodenum through a second stab and leading it out on to the skin.

Brewer in 1910 reported 1 case and Wilms in 1912 6 cases in which they employed the Jenckel procedure. The 2 last named authors have simultaneously adopted the step of allowing the buried tube to pass out of its own neck. In German literature this procedure is frequently referred to as the Wilms-Brewer operation. Wilms could explain the success in his cases only on the basis of the ability of the epithelium lining the ducts to regenerate rapidly along the prosthesis. McArthur a pioneer in this work particularly stressed the point that by constant duodenal and jejunal tug the catheter would ultimately be drawn into the intestine and be discharged per rectum. He reported eight successful choledochorrhaphies over a buried tube.

Feist has collected 24 cases of primary healing with the buried tube method up to 1925. To this number I have been able to add 18 more cases from the literature considered as successes by their authors. A brief summary with the postoperative periods reported follows. Jenckel had 7 cases reported from his clinic by Gerlach as being well 8½, 7, 6½ years later and shorter periods. Wilms reports 6 cases well for periods of from 3 months to 12 months. Verhoogen (10) 1 case, 1 year, Alessandrini 1 case, 6½ years. Doberauer, 1 case 3 months, Kehr (34) 1 case 2 years, Propping 1 case 2½ years. Hagyard 1 case, 6 months. Feist, 1 case 12 months, Voelcker,

2 cases, Lohmeyer, 1 case, Huchsch, 1 case, Martin du Pau, 1 case, Simon, 4 cases, Kuemmel, 1 case, Desplas, 1 case, Gomez, 1 case 4½ years, and Mann 1 case, well 5 months.

Three years after the first operation by Jenckel and 1 year before its publication (Jenckel did not publish it until 1910) Arthur G. Sullivan (59, 60) reported the operation successfully carried out in 8 dogs. The fact that Sullivan was undoubtedly the first to perform this operation in animal experiments, just as Jenckel was the first to perform it successfully in the human, suggests the propriety of calling it the Jenckel-Sullivan operation rather than the Wilms-Brewer operation.

The study of the cited cases prompts the following questions. Does a new duct form? Does the epithelium actually grow in to line the new channel? Does an ascending infection take place? What is the effect of a buried tube on the tissues? How long does the tube remain *in situ*? What happens after the tube passes? What are the end results? It is only fair to state that the literature contains a number of reports recounting frank failures and condemning the method. Enderlen, Propping and Arnsperger were pessimistic about its value. Magnus reported 3 consecutive failures with it, and Naegeli, 2. Brewer's patient developed obstruction symptoms 2 months after the second operation and died of cholemic bleeding. To these cases should be added those of Cahen and of Hagler, the patients dying of liver abscesses 5 and 7 months after the operation. It is safe to assume that failures are less likely to be reported than successes, and that a number of cases originally reported as successes subsequently developed stenosis with its dire effects.

Does a new duct actually form? Jenckel, Verhoogen, Wilms, Pels-Leuden and others answer this question in the affirmative. The explanation according to them is to be seen in the extraordinary regenerative capacity of the epithelium of the extrahepatic bile tracts. The epithelium grows along the prosthesis from the stumps and forms a new epithelial channel. Verhoogen and Wilms see an analogy in the remarkable regenerative capacity of the epithelium lining the urethra. The same

*See discussion in *Zentralbl. f. Chir.* 1923, 19.

opinion is expressed by Judd and Burden as late as 1934 in a paper in which they discuss the histological structure of the common bile duct. They state "The lining epithelium of the common bile duct is possessed of extraordinary power of regeneration and quickly covers any break in its continuity. In fact it grows into and lines a new duct constructed from other tissue as was shown experimentally by Horsley.

I shall attempt to answer the question of new duct formation as well as the question of epithelial regeneration on the basis of post mortem evidence as well as on the basis of experimental data. In passing I wish to quote an opinion advanced by W. J. Mayo (47) in 1916. In discussing the various methods of reconstruction of the common bile duct he had this to say concerning the Sullivan method:

"This is by all means the simplest method of restoring the bile channel but unfortunately the newly formed channel is not mucus lined and we must expect that eventually contraction will take place after the tube slips into the intestine which will ultimately occur.

Does an ascending infection occur? It is my impression that more or less infection occurs in every case. It need not in every instance lead to liver abscesses, as in the cases of Cahen and Hagler but that a variable amount of cholangitis and hepatitis takes place is most evident from the frequent mention in the postoperative histories of these patients of chills fever and jaundice. Jenckel and Wilms believe that formation of an oblique channel in the duodenal wall as *de Witel* will do much to prevent an ascending infection.

The use of a buried tube apparently does not favor formation of stones but that it may lead to pressure necrosis is evident from at least two cases. Thus Freund removed a prosthesis which lay buried for 2 years and which led to stenosis of the papilla of Vater and caused attacks of jaundice and fever. Graff (cited by Feist) removed a tube in a case in which after 10 years of good health it led to formation of liver abscesses.

How soon does the tube pass? That depends principally upon the method of fixation and the kind of suture material used. There is no way of telling how long the tube remains in

the intestinal tract after it has passed into the bowel. In some instances the tube was vomited up.

What happens after the tube passes, as well as the end results themselves, cannot be accurately judged from clinical cases reports of which are limited to short periods of observation. The answer to these is closely linked with the question of whether new ducts are actually formed and whether these ducts are lined by epithelium.

From the evidence thus far adduced it is apparent that the much vaunted regenerative capacity of epithelium of the extrahepatic bile ducts is so far a conjecture rather than an established fact. There remain to be proved at least 2 facts, one that new ducts have actually formed and two that these newly formed ducts were lined by epithelium.

POSTMORTEM FINDINGS

In the consideration of many a clinical phenomenon we naturally turn to postmortem findings for elucidation. A search of the literature on this point brings to light 3 cases in which, after a reconstruction operation of the Jenckel-Sullivan type a postmortem examination was made. In one of these a histological study of the new duct was made.

CASE 1. This case was reported in 1913 by Cahen. Cahen performed a cholecystectomy in a woman for a fibrotic gall bladder containing numerous stones. The common duct was explored and a tube inserted. A biliary fistula resulted. The fistula closed at times giving rise to chills, fever, pain, and vomiting. At a second operation, 7 months later, Cahen found a complete stenosis of the common duct. The patient's condition on the table was desperate. Numerous adhesions and the extent of the gap between the hilum of the liver and duodenum made a direct anastomosis impossible. Cahen sutured a rubber tube into the common hepatic and introduced its distal end into the stomach as *de Witel*. The tube was vomited up about 1 month after the operation. There was an improvement as to symptoms for a short time, later followed by diarrhea, loss of weight, and asthenia. Death took place 4 months after the operation.

Autopsy revealed that death was due to liver abscesses. In the duodenum, 1 1/4 centimeters away from the pylorus, there was found a round opening about 4 millimeters in diameter. When a sound was passed, it led into the common hepatic duct. The papilla of Vater could not be found. The fistula between the hepatic duct and the stomach was com-

pletely obliterated. Instead there developed a communication between the hepatic duct and the duodenum.

Cahen believes that the tube had wandered away from the stomach after the catgut sutures had absorbed. The free end of the tube, according to him now impinged upon the duodenal wall and caused a decubitus ulcer. After the expulsion of the tube from the stomach the oblique canal in the latter became obliterated and the bile found its way into duodenum through the ulcerated portion. The newly formed adhesions pulled up the duodenum close to the liver hilus. When we recall Lahey's experience with formation of spontaneous internal biliary fistulas, we feel that Cahen's exploration is perhaps unnecessarily complicated. The essential feature is the presence of adhesions which brought the duodenum up to the mouth of the hepatic duct. The formation of communication between the two was perhaps nothing more than the formation of a spontaneous internal biliary fistula when the anastomosis between the duct and the stomach became obliterated. Adhesions have approximated the common hepatic duct and duodenum and the effect of bile completed the formation of an anastomosis between the two. In other words, nature had apparently performed a sort of hepaticoduodenostomy. Cahen does not believe that epithelialization of the new channel takes place. He feels that nature plays an important part in the reconstruction by pulling up the duodenum to the hilus of the liver through newly formed adhesions thereby materially shortening the gap. No histological study was made.

The second case reported was that of Desplas.

He resected the hepatic duct for a malignant tumor of pancreatic origin. He inserted a Pezzar rubber catheter into the left hepatic without suturing it there. The distal end was introduced into the stomach, thus leaving from 8 to 10 centimeters of the tube running exposed in the peritoneal cavity. The exposed tube was covered by omentum. The patient recovered from jaundice and gained in weight. Later cachexia and ascites developed because of the presence of a malignant growth but jaundice did not return. Exitus took place 152 days after the operation.

Postmortem examination revealed a large tumor

of the head of the pancreas. The duodeno-pylorus was adherent to the left biliary pedicle. Stomach, liver, pancreas and duodenum were removed *en masse*. When the stomach was opened the tube was found to have passed as far down as the third portion of the duodenum. Between the duodeno-pylorus and the hilus of the liver there had formed a fibrous channel which was found to be intact and which permitted the passage of a sound. Apparently, there had formed about the Pezzar catheter a fibrous channel establishing an anastomosis between the liver and the stomach. The stomach and the duodenum were pulled up by adhesions and adhered to the liver bilus.

Histological examination of the new hepatogastric channel revealed that its proximal portion toward the hepatic pedicle possessed an epithelial lining of the type of hepatic mucosa. The distal portion of the duct was lined by a mucosa containing Brunner's glands and resembling that of duodenal mucosa. One-half of a centimeter of its middle portion contained no epithelial lining. It was made up of connective tissue fibers only. In the liver were found biliary abscesses.

In the discussion Gernez related necropsy findings in his own case (third case).

He operated on a man 60 years of age because of chronic jaundice. The gall bladder, cystic and the common ducts were replaced by fibrous tissue up to the common hepatic. Gernez inserted one end of the tube into the common hepatic duct the other into the stomach. The patient was in good health for 4½ years, at the end of which time he developed jaundice and died. Postmortem examination revealed obliteration of the midportion of the new channel. No histological examination was made.

The findings in the 3 cases suggest that the most important factor in the favorable outcome is played by nature itself. I have again reference to the formation of adhesions which result in pulling up of duodenum and stomach to the liver. This materially shortens the gap between the two bringing about a sort of hepaticoduodenostomy or choledochoduodenostomy or gastrostomy.

In only 1 case that of Desplas was a histological examination made. When one considers that the new channel was relatively short, the fact that its midportion was still devoid of epithelium 152 days after the operation does not suggest much regenerative power on the part of the latter. It would be difficult under the circumstances to say whether the epithelium in its upper and lower portions was newly formed or old. In the third case stenosis took place in the mid

portion of the new channel probably because it contained as in the case of Desplas connective tissue only

EXPERIMENTAL DATA

Sullivan (39-60) was undoubtedly the first in 1908 to perform in dogs the operation of uniting the common hepatic duct with duodenum by means of a buried rubber tube. His technique was as follows: the common duct was cut across and a rubber tube was introduced into and up into the common hepatic duct and secured there by a suture on either side. The tube ran freely in the peritoneal cavity down to the upper border of the first portion of duodenum to which it was secured after the manner of Witzel's gastrostomy. Its end was introduced into the lumen of duodenum through a stab wound. The exposed tube was covered by an omental flap. He had operated in this manner upon 8 dogs without a single mortality. Although he had 8 available animals Sullivan subjected only 1 to a histological examination. This specimen was removed from a dog 10 days after the operation. His pathologist reported that the mucosa had grown upward from the duodenum and downward from the duct into the new formed tube. In its middle portion its walls are made up of peritoneal tissue.

Enderlen and Usti in 1911 produced defects in the gall bladders of rabbits and dogs and covered them with an omental graft. After 19 days the graft was found to be completely covered by new epithelium. About this time formation of glands was noted. The new epithelium was of a low cuboidal type but later became high cylindrical. The graft showed connective tissue proliferation which later underwent contracture.

Arnsperger and Kimura, of Wilms' clinic, performed in 1912 the Sullivan operation in dogs. The tube usually passed about the thirty-fifth day. Their animals died of peritonitis caused in their opinion by premature passage of the tube, bile leakage, or perforation of the new duct at a point at which the omental flap was not well applied. All of the animals developed a stenosis at the point where the new channel entered the duodenum. Only 1 dog did not develop obstruction and jaundice

and this one died of pneumonia 30 days after the operation. They state that epithelialization did take place in some of the dogs, but do not mention any histological study. Gross inspection is obviously no reliable criterion.

In 1913 C. B. Davis and Dean Lewis made in dogs tubes of fascia taken from the sheath of the rectus muscle, and placed them about a defect in the common duct. In their first series 3 dogs survived 2 months. In a dog which survived 65 days stenosis took place at the duodenal end. The fascia remained alive in all cases. The histological report was to come later.

In 1918 Horsley attempted in dogs to substitute an everted external jugular vein for the common bile duct. The vein was stitched to the common hepatic, and the distal end was introduced into the duodenum by a sort of modified Witzel technique. He operated in this manner on 16 dogs. Most of the animals died of bile leakage at the suture line of the duct with the vein. Horsley considered the final results unsatisfactory and invoked a biological law to explain the contracture which took place in every case in which the dog survived the operation. The irritating effect of bile upon tissues not adapted to it caused inflammation with subsequent contracture. In spite of the discouraging results Horsley states, "That epithelium does grow at least over a portion of the reconstructed duct is shown in one section (23 days old). Columnar epithelium has grown a considerable distance over on the transplanted vein."

Somewhat more ambitious experiments accompanied by photomicrographs of histological sections were reported by Seulberger and Poellwein in 1926. These authors made three groups of experiments. In group 1 anterior defects in the choledochus covered by omentum they did not observe the slightest trace of epithelial regeneration in specimens 391 and 113 days old. The defects were not very large. In groups 2 and 3 choledochogastrostomies and choledochoduodenostomies *a la* Sullivan the newly formed ducts invariably became stenosed. No epithelialization was noted in the granulation tube even in specimens 100 days old.

Latten (39-40) believed that diverting the

flow of bile away from the common duct would favor healing of defects. He performed a series of experiments in dogs in which a metallic tube was introduced into the common duct through a small incision in the gall bladder. The tube could be removed at a later date by means of a string attached to it. By means of two tight ligatures a portion of the common duct was caused to undergo necrosis. This area was covered by an omental graft. The tube was removed from 3 weeks to 2 months later. The animals were sacrificed 3 to 4 months after the operation. In 6 of 7 dogs the regenerated duct exhibited a complete mucosal lining. In spite of it all of the ducts exhibited marked narrowing with dilatation above.

In a second series Latten utilized the trachea of a guinea pig, of a lark, and a pigeon quill to bridge a 1 centimeter defect in the common duct of a dog. In 7 experiments the prosthesis passed of its own will and epithelialization took place.

Museneczek's experiments published in 1926 represent a distinct advance. He operated on a larger number of dogs than any one before him. Museneczek emphasized the fact that the duodenum was found in each postmortem examination to be plastered against the liver. Curiously enough this phenomenon emphasized by Cahen in a clinical report in 1913 was not observed in animal experiments until the reports of Museneczek.

Museneczek operated on 53 dogs. In a group of 25 he attempted vein transplantation. The results were so poor as not to justify an attempt at analysis.

In another group of 28 dogs he made cuff excisions in 9 and in the rest either a typical or a modified Sullivan operation. His mortality was high. In a group of 7 Sullivan operations 6 died of peritonitis between the third and ninth postoperative days. Of 28 animals 26 developed stenosis, and in these there was not found a trace of epithelialization. In only 2 dogs did there not develop a stenosis. Museneczek was much impressed by the fact that in these two the tubes remained *in situ*. They showed no infection of bile. The duodenum as in the rest of his animals was plastered up against the liver. The new ducts were

Fig. 1 a and b. Technique of application of tube

therefore quite short, about 2 centimeters in length. They were lined by epithelium but whether this was new or old epithelium brought together the author did not feel certain. He was not sure that one was justified in speaking of a 'new duct'. So long as the tube remained *in situ* the danger of stenosis was lessened. He would therefore advise that the tube be made to stay in as long as possible.

PERSONAL EXPERIMENTS

A comparison of results obtained in reconstructive work on the bile ducts in the two fields, the clinical and the experimental, reveals that they were much inferior in the latter. The reason assigned was the smallness and the delicacy of these structures in the experimental animal. While this is true, it may be pointed out that while the surgeon is frequently called upon to operate in the presence of baffling adhesions, cholemic bleeding, and inflammatory states, the experimenter is always operating in a clean field and upon normal structures. Schrager and Ivy have correctly pointed out that a special knowledge of conditions as they obtain in a dog and an adoption of a suitable technique are just as essential to success here as elsewhere.

The number of successful experiments in any one report was too small to justify drawing conclusions therefrom. Frequently post

Fig. 2. Transverse section, dog 8.

Fig. 3. Transverse section, dog 21.

mortem examinations lacked accuracy and only in a few instances were there histological examinations made. Sullivan subjected to a histological study only one specimen although he had 8 surviving animals. For some reason he had the specimen removed on the tenth postoperative day—a period entirely too brief to test the regenerative capacity of epithelium. The pathologist's report is ambiguous on the crucial point. He states that the midportion of the new duct consisted of peritoneal tissues whereas the question in point is whether or not this tube of peritoneal tissue (omentum) was lined by epithelium.

Horsley submitted one new duct (23 dogs) to a histological study and declared that it was at least partly lined by new columnar epithelium. Young epithelium is cuboidal columnar epithelium suggests mature cells.

Seulberger and Poellwein do not state the exact number but seem to have made a histological study of several specimens. These authors have not observed any effort on the part of the epithelium to proliferate.

Musenecck operated on more dogs than any experimenter in the field before him. His postmortem observations were characterized by greater accuracy. He did not miss the importance of adhesions and reports that the duodenum in every case was adhered to the liver. On the other hand Musenecck, together with the rest of the experimenters, apparently never observed a duodenal ulcer though he had an unusually large number of postopera-

tive stenoses of the bile duct. In my animals the incidence of duodenal ulceration among those exhibiting varying degrees of bile duct stenosis was very high.

An attempt was made in my own work to obtain a sufficiently large number of successful experiments to justify drawing conclusions therefrom. By a successful experiment I mean one in which the animal survived a typical operation was allowed to live a suitable period of time and was sacrificed at will. A careful postmortem examination completed each successful experiment. I have operated on 135 dogs and can report on 28 completed experiments.

The incidence of peritonitis, of death from bile leakage of ascending infection leading to liver abscesses was very high in the beginning of my work. Dogs are undoubtedly very sensitive to spilling of bile in the peritoneal cavity. A number of them died of bile leakage within the first 24 or 48 hours without developing signs of peritonitis. As the work progressed the ducts became considerably larger and the postoperative mortality was reduced to an insignificant minimum. The use of nembutal anesthetic (Abbott) adopted in the later period of my work proved an important factor in the reduction of anesthetic fatalities.

Experiments were planned so as to throw light upon the ability of ductal epithelium to proliferate and fill in large longitudinal defects (Group I), small longitudinal defects (Group II) as well as to grow along a prosthesis and fill in a transverse gap (Groups III and IV).

Fig. 4. Transverse section dog 1

TECHNIQUE

Group I A rubber tube French catheter No. 8 or No. 10 was introduced into the common bile duct through a small incision. The tube was passed upward and was fixed there by tying a ligature about the duct and the tube or by placing a suture on either side of the duct so as to include in it the tube and the duct. The lower end of the tube was made to pass along the duct through the papilla of Vater into the lumen of duodenum. A variable amount of the duct wall was now destroyed. Since it was not possible to measure accurately the width of the defect because the tube forced the edges of the wound apart an attempt was made to estimate the width of the defect in terms of percentages of the circumference of the duct. The length could be readily measured. The defect was covered by a flap of the gastrobepatic omentum pulled under the posterior aspect of the bile duct and laid over the defect. A few interrupted sutures were employed to fix the flap in place so as to make a complete omental tube about the defect (Fig. 1 a and b). This step was found to be quite useful later in recognizing the reconstructed duct in postmortem examination. The adherent omental flap indicated the area (Figs. 1 and 2). The length of the defect in the group was usually from just below the cystic duct down to the superior border of duodenum almost the entire length of the supraduodenal portion of the duct. The width of the defect was from 50 to 70 per cent of the circumference of the duct in several instances only a narrow posterior strip of the duct wall being left.

Group II Essentially the same technique was employed, the defect varying from that

Fig. 5. Transverse section dog 24

of a mere longitudinal slit in the anterior wall to not more than 40 per cent of the circumference of the duct.

Group III This group was carried out according to Sullivan's technique. A rubber tube was introduced into the common bile duct and was fixed there just below the cystic duct by a suture made to pass through the tube and the duct on each side of the duct. The duct was resected below the sutures and the lower stump at the border of duodenum was ligated with silk. The tube running freely exposed in the peritoneal cavity was laid upon the superior anterior wall of the first part of the duodenum to which it was now fixed for about a distance of $1\frac{1}{2}$ to 2 centimeters after the manner of Witzel's gastrostomy technique. The lower end of the tube was introduced into the lumen of the bowel through a stab. Omental tissue drawn from the lesser omentum the greater omentum or both was used to make a tubular investment for the exposed tube (Fig. 1 a and b).

Group IV Cuff excision. A rubber tube was introduced as in the previous group. This tube was secured just below the cystic duct by a suture on either side of it. Another pair of sutures fixed it to the duct just above the superior border of duodenum. The intervening duct was cut away. The gap was covered by an omental flap.

ANALYSIS OF RESULTS

Results were analyzed in the light of the following points

1. Occurrence of ascending infection

Fig. 6 High power photomicrograph, dog 5.

Fig. 8. Photomicrographic section showing normal tissue.

- 2 Incidence of stenosis and its relation to the ascending infection
 - 3 Influence of tube remaining *in situ* on the occurrence of ascending infection
 - 4 Epithelial regeneration in four groups

Fig. 7 Adhesion of duodenum to under surface of liver

The number of successful experiments was 28 Group I—10 dogs Group II—6 dogs Group III—10 dogs and Group IV—2 dogs.

Of a total of 28 dogs, 5 did not develop an ascending infection. Eight exhibited a high grade of infection and in 15 it was mild. The severe grades of ascending infection were characterized either by acute lesions, such as purulent cholecystitis, purulent cholangitis with multiple liver abscesses or by more chronic lesions, such as a thickened gall bladder or a bobnailed liver.

The milder grades of ascending infection manifested themselves by the presence of adhesions between the gall bladder and the diaphragm the stomach duodenum etc. The gall bladder was frequently enlarged its walls thickened and the characteristic slate blue color changed to a whitish or greyish. It was interesting to note in these cases the presence of milky radiating scars on the surface of the liver so called subcapsular scars considered characteristic of a gall bladder infection in man. They were most prominent over that area of liver overlying the gall bladder. These subcapsular scars were seen only at a post mortem examination never at operation.

When we examine the relation of ascending infection to stenosis, we find that all of the animals exhibiting stenosis likewise exhibited an ascending infection. In Group I dogs 3, 8 and 24 did not develop a stenosis of the reconstructed duct. Dogs 3 and 24 did not exhibit any evidence of an ascending infection and

dog 8 a very mild one. In Group II dogs 6, 14, and 20 did not develop duct stenosis and in dogs 14 and 20 no ascending infection was evident. When we examine Group III, we find that while dogs 16, 21, and 22 had no stenosis only dog 16 did not exhibit signs of an ascending infection. Dog 22 had a mild and dog 21 a severe infection in the absence of a stenosis. From this it is apparent that while stenosis never failed to be associated with an ascending infection, its absence did not save dogs 8, 19, and 22 from a mild and dogs 6 and 21 from a severe infection. Furthermore in dogs 19, 21, and 22 the tube did not pass. The contention of Musenczek that the presence of the tube in the duct is a safeguard against an ascending infection because it prevents stenosis is therefore incorrect. While the tube prevented stenosis it was not able to prevent an ascending infection in dogs 19, 21, and 22. It may be assumed that the responsible factor in the 5 dogs without stenosis was interference with the closing mechanism of the sphincter of Oddi.

The question of epithelial regeneration. That ductal epithelium possesses a capacity for regeneration could be safely assumed *a priori* on purely biological considerations. It is well known that epithelial liver cells as well as epithelial cells lining intrahepatic ductus biliferi possess a high degree of regenerative power. However it is likewise known that under certain conditions these cells perish and fail to regenerate. Our query therefore, should be not so much can the ductal epithelium regenerate but rather, can it regenerate under certain conditions?

In Group I there were extensive defects running almost the entire length of the supraduodenal portion of the choledochus and involving from 50 to 70 per cent of the circumference of the duct. Of 10 dogs 4 showed complete epithelial regeneration, 6 none.

In Group II, with small defects running from a longitudinal slit to defects not larger than 40 per cent of the circumference, all of the ducts healed by epithelial proliferation.

The Sullivan group consisting of 10 dogs, did not exhibit, in a single instance, any epithelial ingrowth in the new channel—this despite the fact that the new channel in each

was much shorter than the reconstructed duct at the time of operation (Fig. 3).

In Group IV one dog showed no epithelial regeneration and the other showed a markedly hypertrophic epithelial lining. However I believe it to be old epithelium. The duodenum was adherent to the liver shortening up the original duct to one half its original length. The amount of duct resected was 2 centimeters. It is easy to see that the stumps of the resected duct became approximated in that way. Furthermore young recently regenerated epithelium does not exhibit such marked papillary evagination as did this one.

If we enquire further into the question of why in Group I 4 ducts displayed complete epithelial regeneration while in 6 there was none we find a ready answer in the histological picture of these ducts.

Dog 3 with a large defect in the common bile duct had an uneventful recovery. The animal never exhibited jaundice its nutrition was good and general health perfectly normal. It was sacrificed exactly one year after the operation. At postmortem examination the peritoneum was found to be normal. The first portion of the duodenum was adherent to the liver. Liver, stomach, and duodenum were removed together. The duodenum was slit open on its mesenteric side. The tube was not to be seen. The papilla was visualized and a sound introduced into it passed upward into the hilus of the liver without meeting any obstruction. The common bile duct appeared smooth somewhat larger than normal, and whitish in appearance. All of the supraduodenal portion of the duct was removed for histological study. Transverse serial sections were made and were stained with hematoxylin and eosin. In all of the sections the epithelial regeneration was practically complete. The original epithelium was readily recognized by its marked papillary evagination and a marked tendency to formation of parietal sacculi. The new epithelium was rather poorly developed. There was no evidence of inflammatory reaction in the wall of the regenerated duct. Gall bladder sections and liver sections appeared normal.

Dog 8 The duct was very fine. After introduction into it of a ureteral catheter No. 6, all that was left of the duct was a strip of the posterior wall. The defect was covered by an omental flap. The work was considered unsatisfactory. The dog however remained in good condition and was sacrificed 106 days later. On postmortem examination the peritoneum was found to be normal. The gall bladder was pinkish-grey. Its fundus was attached to the dome of the diaphragm by a broad adhesion. The first portion of the duodenum was adherent to the inferior aspect of the right lobe of the liver. On the surface

of the liver were seen milky radiating subcapsular scars. Liver, stomach, and duodenum were removed *en masse* and laid on the table for more detailed study. The duodenum was opened on its mesenteric side. Pressure on the gall bladder caused thick bile to flow from the papilla. A probe passed up without encountering any obstruction. The duct appeared somewhat larger than normal felt thicker and presented a smooth glistening appearance. Transverse sections of the duct showed complete epithelial regeneration. The epithelium was quite normal. It displayed papillary evaginations and panetel sacculi (Fig. 2). Comparison with a normal duct of a dog (Fig. 4) demonstrates that there is no inflammatory reaction in the wall of the regenerated duct.

As a contrast to dogs 3 and 8 I shall present the history of dog 1.

Dog 1. The same operation was performed here as in dogs 3 and 8. Three weeks after the operation the animal exhibited signs of biliary obstruction, but these had disappeared and the animal remained in a fair state of nutrition. He was sacrificed 106 days after the operation. Postmortem examination showed the following. The liver was much enlarged. There were firm adhesions between the liver, duodenum and stomach. All visible extrahepatic ducts were tremendously enlarged. Liver, stomach, and duodenum were removed together and the duodenum and stomach were slit open. Pressure on the fundus of the gall bladder caused a watery viscous fluid to exude from the papilla. A probe passed up the papilla became arrested just above the superior border of the duodenum. The duct above the constriction was tremendously enlarged. The point of obstruction corresponded to the site of the lower ligature tied about the duct and the tube. The supraduodenal portion of the duct was removed for histological study. Transverse sections showed the lumen of the duct for the greater part, at least 70 per cent of it, devoid of any epithelial lining. Whatever epithelium there was exhibited poor development, total absence of papillary evaginations and of gland formation. The duct wall itself was tremendously hypertrophied. It consisted of enormous amounts of connective tissue. Here and there were to be seen areas of marked infiltration with polymorphonuclear leucocytes (Fig. 4).

Dog 2. In this animal there was not a trace of epithelium. The wall was of extraordinary thickness.

The same histological picture was found in all 6 animals which did not show any epithelial regeneration. The ducts which healed by epithelial proliferation exhibited in all four instances a wall of approximately the thickness of a normal duct. Conclusion may be drawn from Groups I and II that ductal epithelium is capable of growing and filling in small as well as extensive longitudinal defects, pro-

vided that its blood supply is not compromised by an excessive inflammatory process. Excessive reaction with its superabundant connective tissue undergoes a later contracture with the development of a stenosis. There was no instance of epithelial regeneration in the presence of a stenosis in all of the series save one. This exception was dog 13 in Group IV. However as pointed out before, we were dealing here most likely with old epithelium brought together rather than with new epithelium.

Epithelial growth is influenced more by an adequate blood supply than by the extent of the defect. This was strikingly demonstrated in dogs 24 and 25 of Group I. In dog 24 the defect amounted to 1.7 centimeters in length by 70 per cent of the circumference. It was sacrificed 95 days later. There was no evidence of an ascending infection, or of stenosis. Epithelial regeneration was complete. The duct wall showed no inflammatory reaction (Fig. 5 dog 24).

Dog 25. The defect was smaller than in dog 24. It amounted to 1.5 centimeters in length by 50 per cent of the circumference. It was sacrificed 81 days after operation. Mild stenosis of the duct was present. There were no signs of a mild ascending infection, such as a thickened gall bladder subcapsular scars on the liver surface, and a hobnailed appearance of the liver. A partly healed gastric ulcer was found. Histological sections demonstrated that epithelium was absent in many parts, and that wherever present, it was poorly developed. The duct wall was abnormally thick and consisted of bundles of connective tissue. These were seen to surround epithelial glands. One could easily see how later contracture would choke the epithelial elements (Fig. 6).

In the Sullivan group of 10 dogs there was not a single instance of epithelial proliferation in the new channel. The same was true of Group IV. Therefore it is evident that epithelium will not grow along a prosthesis to fill a transverse gap. How can we explain the successful results of Jenckel, Verhoogen and Wilms? Verhoogen's case was repeated in dogs 4 and 13. I feel that I am justified in rejecting the theory of epithelial proliferation along the prosthesis on the basis of post mortem evidence of Desplas and on the basis of my results with the Sullivan group. Explanation must be sought in the formation of

adhesions between the duodenum, pylorus, and the liver. The effect of this phenomenon is obvious. It shortens materially the gap to be bridged. It is easy to see that in Verhoogen's case the stumps of the duct were brought together in just this manner. It would be difficult, if not impossible to explain the *modus operandi* of repair except on this basis. Cahen was first to call attention to the rôle played by these adhesions in the description of the postmortem examination of his patient, in 1913. Museneek emphasized its occurrence in experimental work. In my own material it took place in all but 1 animal (dog 24). The length of the duct in this dog appeared unusual. I have made an attempt to measure the length of the choledochus at the time of operation and again at postmortem but this was impossible because of adhesions and altered relations. It would however be no exaggeration to state that the new ducts were markedly shortened. In the dog the duodenum is freely movable. Furthermore, in my work it was necessary to hold and exert some pull upon the first portion of the duodenum in order to expose the free edge of the hepatoduodenal ligament. Mechanical trauma with perhaps some spilling of bile furnished sufficient irritation to produce adhesions. While in reality a mild pathological complication it no doubt played a most favorable part in the outcome of successful cases (Fig. 7).

Duodenal and gastric ulceration in dogs with stenosis of the common bile duct. That the exclusion of bile from the intestine may lead to development of duodenal or gastric ulcers has been recently pointed out by Kapsanow, Kim and Ivy, Berg and Jobling, and others. I was not familiar with this fact until an acute perforation of a duodenal ulcer in dog 5 forcibly called my attention to it. Observations on this point were made in 20 animals. Nine developed stenosis and of these 9, 7 had ulcers. Duodenal ulcer occurred alone four times, gastric alone twice, duodenal and gastric once. There was one perforation. The incidence of occurrence was 78 per cent. All of the animals exhibited more or less hepatitis.

The cause of ulceration may be at least in part due to interference with the process of alkalization of acid chyme by the bile.

There is evidence to believe that hepatitis may play an important part in the causation of these ulcers.

CONCLUSIONS

1. Epithelium lining the extrahepatic bile ducts is capable of regeneration under favorable conditions.

2. Small longitudinal defects will heal readily by epithelial regeneration, a fact familiar to the clinical surgeon and borne out by the experiments in Group II.

3. Longitudinal defects, even if extensive may regenerate under favorable conditions, namely, in the absence of marked inflammatory reaction in its walls as demonstrated by Group I.

4. Ductal epithelium is not capable of growing along a prosthesis and lining a gap as was demonstrated by Groups III and IV.

5. Obstruction to the flow of bile invariably leads to an ascending infection. The presence of a tube in the bile duct, even with the absence of a stenosis, leads to infection presumably by interfering with the mechanism of the sphincter of Oddi.

6. Diversion in dogs of bile from the duodenum results in a high percentage of duodenal and gastric ulcerations invariably accompanied by a hepatitis.

7. Dogs die in from 24 to 48 hours from the effect of spilling bile into the peritoneal cavity without signs of peritonitis.

8. Omental covering is the ideal safeguard against bile leakage and infection.

9. Excessive inflammatory reaction at the site of repair is prejudicial to epithelial growth. (The use of absorbable suture material and omission of drain would tend to minimize such reaction.)

10. The Jenckel-Sullivan or Wilms-Brewer operation can be regarded only as a measure of necessity justified under certain desperate conditions rather than as operation of choice. Formation of adhesions with their subsequent contracture and pulling up of the duodenum to the porta hepatis is the more plausible explanation of the *modus operandi* of healing in an occasional successful case than the problematic growth of ductal epithelium along a prosthesis or new channel.

SUMMARY

Causes leading to stenosis of the extra hepatic bile ducts were discussed and clinical evidence regarding their regenerative capacity educed. From the analysis of the results of various methods of reconstruction it is apparent that the stumbling block to success is the question of adequate blood supply to the new channel. That is particularly true of the method of fistula implantation and also of flap methods. The method of bridging a gap with a rubber tube was given particular consideration. Clinical evidence regarding its efficacy was found to be contradictory. Adherents of the method concluded that success was explainable on the basis of extraordinary regenerative capacity of ductal epithelium. The epithelium they believed grew along the prosthesis and lined the new channel.

The question of regenerative capacity of ductal epithelium was studied experimentally. It was found that epithelium will proliferate and fill longitudinal defects even if extensive provided there be no excessive inflammatory reaction at the site of repair. The question of blood supply to the epithelium was again found to be the determining factor. It was found that epithelium will not grow along a tube and will not regenerate a transverse gap. This experience coincides with the postmortem evidence of clinical cases.

Importance of adhesions as a factor in favorable outcome was emphasized. This idea receives its support from the observations of Cahen, Lahey, Muneneck and my own experimental work. There is no one satisfactory method at the present time of dealing successfully with cases of extensive bile duct obliteration in which direct anastomosis is not possible.

CARCINOMA OF THE OESOPHAGUS¹

WILLIAM L. WATSON M.D. F.A.C.S., New York

Assistant Attending Surgeon, Memorial Hospital

THE problems presented by tumors of the oesophagus have engaged the attention of many capable surgeons pathologists internists and endoscopists during the past 30 years. The radiologist being concerned with the diagnostic and the treatment phases of the problem has had a twofold interest in the disease. This widespread interest has led to the accumulation of considerable literature on the subject.

Much original thought, experimentation and imagination have gone into the development of the many varied forms of treatment which have been advocated at one time or another for the cure of cancer of the oesophagus. Noteworthy among these methods was the advent of radium as an intra-oesophageal method of irradiation. This method was first proposed in 1904 and soon the literature was quite flooded with descriptions of new apparatus, new dosages, new filters and new methods for accurately locating the radium in the oesophagus. This period began so hopefully was not however followed by reports of cures or even good palliative results and the method fell somewhat into disfavor.

A great deal of attention had been directed toward the development of a procedure for radical removal of carcinoma located in the oesophagus. In several of the larger European clinics some significant results had been obtained in the removal of the cervical and intra abdominal portions of the oesophagus for carcinoma. The first successful intra thoracic oesophagectomy was accomplished in this country by Torek in 1913. With this success oesophageal surgery was thought to have reached a point where it could be called the answer to the treatment problem. Unfortunately surgery has not fulfilled its early promise. Such a general lack of success would lead one to suspect that those who have advocated these various methods of treatment have been unjustifiably optimistic.

A careful study of the clinical course of the disease, the anatomy of the organ involved

and the postmortem material available will show that patients with cancer of the oesophagus should be given palliative treatment as a routine measure and that only in the very unusual early case should intra-oesophageal irradiation or radical surgery be attempted. The cured case will be a medical curiosity.

The material for this report has been taken from the Memorial Hospital records accumulated during the 13 year period between 1918 and 1931. Five hundred and six (506) patients with carcinoma of the oesophagus were admitted to the hospital and of this number there were 267 patients with positive biopsy diagnoses. For the past several years all patients have had biopsies removed for diagnosis. Previously this was considered an unnecessary risk, and for this reason, biopsies were seldom taken from the early patients. The entire material of 506 cases has been summarized in this report, but the statistical portion is based on a study of only those cases with positive microscopical sections. To include the cases without biopsy would be quite justifiable but would not appreciably alter the statistics and might lead to some criticism as to the accuracy of the figures.

Twenty nine patients suffering from oesophageal obstruction thought to be cancer were admitted and later their obstruction was proved to be due to such benign causes as spasm, syphilis, non specific ulcer acid or alkali burns and idiopathic stenosis. Most of these patients recovered under appropriate dilatation measures.

An intimate knowledge of the anatomy of the oesophagus is necessary in order to understand the dangers and difficulties encountered in the treatment of cancer in this organ. The oesophagus is a thin walled tube about 25 centimeters in length, developed from the foregut. It differs from the other portions of the intestinal tract in that it lacks an outer serosal covering, a distinct surgical disadvantage. The oesophagus is richly supplied with lymphatics in the submucosal and muscular coats,

thus providing a submucous pathway for the dissemination of cancer. Mucus-forming glands are found throughout the oesophagus and undoubtedly give rise to the adenocarcinoma which occurs in this organ. The oesophagus is surrounded throughout its length by important and vital structures (Fig. 1) which are invaded early in the course of oesophageal cancer.

GROSS PATHOLOGICAL ANATOMY

Gross examination of a number of oesophageal carcinoma specimens demonstrates three definite types. First there is the bulky, polypoid projecting, or vegetative type which usually grows into the lumen of the oesophagus causing obstructive symptoms at a relatively early stage (Fig. 2). Second, there is the shallow ulcerating type causing early symptoms of mediastinal involvement such as pain and backache (Fig. 3). Metastases and obstructive symptoms may be absent. This type tends to perforate the musculature of the oesophagus early and to invade the aorta, bronchi or trachea. Perforation into one of these vital structures causes death, most often by sudden hemorrhage due to the perforation of the aorta or other large vessels (Carr, Polson and McIntosh Heitzmann). Third, there is the hard, infiltrating scirrhous type which invades the oesophageal wall, and which may encircle the lumen causing fixation of the walls and producing symptoms of obstruction. It may be superficially ulcerated (Fig. 4). The extension of the disease by way of the submucous lymphatics is shown in Figure 5. Here we find an outcropping of tumor tissue several centimeters above the primary growth.

Oesophageal growths are usually divided into another three groups according to their location in the upper, middle or lower third of the oesophagus. Recently it has become the custom to locate the lesion by its relation to the various anatomical constrictions of the oesophagus. This method is more accurate than the former. Table I shows the relative frequency of cancer of the oesophagus at the three levels.

The most plausible reason for the relatively high frequency at the lower third (about 50 per cent) is the increased irritation due to the

TABLE I—DISTRIBUTION OF GROWTHS

slowing of hot liquids at the diaphragmatic constriction and to the frequent presence of chronic spasm in this location.

MICROPATHOLOGY

In the Memorial Hospital series of 267 cases there were 243 squamous cell lesions, 19 adenocarcinoma and 5 of the transitional cell type. The adenocarcinoma were all located in the lower third of the oesophagus. Guisecz reported a series of 1,413 cases, five sixths of which were squamous cell carcinoma and one sixth adenocarcinoma. He did not once encounter a sarcoma. Jackson reported 671 cases of which 316 were adenocarcinoma, all located in the lower third of the oesophagus, 2 lymphosarcoma, 2 round cell carcinoma and the remainder, 337 cases squamous cell carcinoma.

With 267 positive biopsies it was found that the material was suitable for grading in 227 cases. This work was done largely by Dr. F. W. Stewart. Table II shows the relative frequency of the different grades and the number of cases which were diagnosed as histologically susceptible to radiation. In this series it is seen that there were only 39 cases (12.7 per cent) in the grade 3 group, 14 (6.1 per cent) of which were reported as probably radiation sensitive. Only 30 of the cases (13.2 per cent) in the grade 2 group were probably radiation sensitive. About 18 per cent of the carcinoma of the oesophagus are radiation sensitive. This evidence does not agree with Guisecz's impression that oesophageal cancers are as a rule susceptible to radiation. There were no cases in the grade 4 group. Figure 6 shows photomicrographs of the three grades of carcinoma which occur in the oesophagus.

Broders and Vinson reported 220 cases with 90 per cent in groups 3 and 4 and no grade 1

cases. In the Memorial Hospital series 83 per cent of the cases fell in the groups 2 and 3.

AUTOPSY FINDINGS

Most of our cases are hospitalized for a short time only. For this reason the autopsy material is limited to 27 cases. Thirteen cases (48 per cent) coming to postmortem showed no evidence of metastasis. It must be borne in mind however that a careful autopsy does not always demonstrate the presence of early metastatic deposits. There was gross lymph node involvement in 12 (44 per cent) of the 27 cases (Fig 7). In 7 cases (26 per cent) there was extension to or actual rupture into the trachea or bronchus. In 2 cases (7 per cent) the disease ruptured into the aorta causing sudden fatal hemorrhage. Pneumonia was a contributory cause of death in 13 cases (48 per cent). 12 were bronchopneumonias, and 1 was lobar in type. In 4 cases hemorrhage was the cause of death. Other causes were peritonitis 3 cases starvation asphyxia cardiovascular disease generalized carcinoma toxæ, septicæmia, and diarrhoea, each 1 case. In one case the cause of death was not determined due to a limited autopsy permit.

ETIOLOGY

It is not possible to give exact etiological data. However it is now quite generally believed that there are certain definite factors which predispose to oesophageal new-growths. In the oral cavity it has been shown that broken irregular or sharply worn teeth ill fitting plates, leucoplakia excessive pipe smoking syphilis and intra-oral sepsis are definitely irritating factors in the causation of intra-oral carcinoma. Similar factors prepare the oesophageal mucous membrane for cancerous changes. Badly kept teeth intra-oral sepsis, and ill fitting plates tend to cause hasty and incomplete mastication which makes

it necessary for the oesophagus to handle masses of food which are large and hard. A large hard bolus of food causes a certain amount of trauma and inflammation of the oesophageal mucous membrane. The passage downward of such a bolus of food would be slowest at the point of anatomical constriction and the resulting trauma would be greatest at these points. This trauma causes irritation which may lead to spasm, and with it further slowing of the food bolus and later stagnation, oesophagitis, ulceration and possibly tumor.

Thermal irritation is probably the most constant factor predisposing to carcinoma of the oesophagus. The frequent drinking of copious amounts of excessively hot tea is a history frequently obtained from the Russian patient suffering from cancer of the oesophagus. This fact is especially significant when it is seen that 46 per cent of the foreign patients in our series were born in Russia. There were more Russians than native born patients (Fig 8). In China, cancer of the oesophagus is very uncommon among the women. This is said to be due to the fact that they eat after the men have finished and the rice is not so hot. The women of Scotland drink excessively hot tea and Turner has reported that cancer of the oesophagus is more common with them than it is among the men.

Leucoplakia of the oesophagus is being recognized more frequently due to the increasing popularity of the oesophagoscope. It is a very common condition. Schaefer found it to be present in 60 per cent of 200 non-cancerous cases coming to autopsy. Clinically and pathologically the process is the same as that seen in the oral cavity (Sharp) where it is a definite etiological factor.

Gulrez who has had a very extensive experience with oesophageal cancer thinks the excessive use of alcohol spiced food and tobacco are factors in many of his cases. He has noted also that the onset of cancer of the oesophagus is often definitely attributed by the patient to some particular mental or physical shock. He observed an increase in the incidence of cancer of the oesophagus in young adults following the World War and thought the following sequence of events had taken place first an emotional upset then an oesophageal cancer.

Fig 1 Showing the position and relation of the oesophagus in the cervical region and in the posterior mediastinum. Seen from behind. (From Polter and Charpy.)

phageal spasm followed by stasis, oesophagitis, contracture, or inflammatory stenosis, and finally cancer. Jackson has pointed out the fact that cancer of the oesophagus often occurs in patients who have had oesophageal spasm for years. Guisez reported 70 such cases.

Mosher has demonstrated the presence of thin webs and pouches in the oesophagus. These may have an etiological bearing as may also the cicatricial contractures which result from the swallowing of caustic solutions or the healing of peptic or traumatic ulcers.

Syphilis does not play an important rôle in the etiology of the disease. It was present in only 7 per cent of our cases. Lamy found syphilis present in 10 per cent of his cases and Jackson reported 14 positive Wassermann re-

actions in his 671 cases (2 per cent). carcinoma of the oesophagus reported in which luetic or tuberculous co-existed. One case reported by Gregg showed cancer syphilis of the oesophagus. Syphilis is the general run of the population, in the same proportion as it was in cancer cases.

INCIDENT

Cancer of the oesophagus is more than 2.5 per cent of the population admitted to Memorial Hospital, New York City during the year 1910. The deaths caused by cancer due to cancer of the oesophagus

Fig. 2.

Fig. 2 Postmortem specimen showing large bulky squamous carcinoma of the esophagus invading the trachea. Bronchopneumonia was the cause of death in this case.

Fig. 3.

esophagus at its lower third. Microscopic section of the lesion showed squamous carcinoma, grade 2 radiation resistant.

Fig. 4. A carcinoma of the middle third. Microscopic section showed squamous carcinoma, grade 3.

Fig. 4.

of 3.38 per cent. Abel reports that cancer of the esophagus makes up 5 per cent of all cancer cases. Ernst 6 to 10 per cent and Litten 8.20 per cent. It is amazing that this very fatal disease should have such a high incidence. The figures, I believe, will appear high even to one actively engaged in cancer work.

SEX

It is well known that this disease is much more common in the male sex. Guiseux with 1,430 cases reported 6 males to 1 female. Jackson with 671 cases, reported 87 per cent males, and in our series of 267 cases there were 225 males (84.3 per cent) and 52 females (15.7 per cent) (Figs. 9 and 10).

AGE

The youngest patient with proved carcinoma of the esophagus treated at the Memo-

rial Hospital was 35 years old and the oldest was a man of 80. The average age of the females was 53.8 years while the average for the males was 57.4 years. Cummins first called attention to the fact that the female sex developed carcinoma of the esophagus at an earlier period of life than did the male. Our figures agree fully with his findings.

SYMPTOMATOLOGY

The onset of carcinoma of the esophagus is most insidious, and although we have the ready means (esophagoscopy) for making a positive diagnosis, it is still a fact that one seldom sees a patient in the early stages of this disease. The function of the esophagus is to transport food from the pharynx to the stomach and this function is seriously interfered with only late in the course of the disease. Then too the patient will masticate

his food more thoroughly after he notices that large particles of food have a tendency to stop or "stick" part way down. Such periods of temporary dysphagia tell a story to the physician but unfortunately the patient pays little heed to such a matter and will mention it only when a careful history is obtained.

When definite persistent dysphagia occurs and the patient seeks relief for it his disease is usually quite advanced. It is most unfortunate that dysphagia should so often be the first symptom of oesophageal new growth. In our series 64 per cent of the patients gave as their first symptom difficulty in swallowing solid foods. If the mortality from this disease is to be reduced, earlier diagnoses must be made and earlier symptoms must be sought for and detected. When dysphagia, dehydration and emaciation exist the disease is hopelessly advanced. Dysphagia is not an invariable finding in oesophageal carcinoma, it may be absent in patients dying of the disease (Cabot Emanuel). In cases of so called "cardiospasm" and other nervous disorders dysphagia may be present for 20 years or more unrelated to malignant disease in the oesophagus. Dysphagia is thus an unreliable symptom and of little aid in making an early diagnosis.

The following vague early but less frequent symptoms noted in this series seem worth mentioning in the interests of early diagnosis. A feeling of substernal pressure was complained of in 6 cases, anorexia, 4 cases, feeling of obstruction 4 cases, hic coughs, 2 cases, hoarseness, 2 cases, difficulty in breathing, heartburn and increased mucus in the throat each 1 case. Foul breath is a common symptom.

The oesophagus is not supplied with sensory nerve fibers and is in itself insensible to pain so that when backache, substernal discomfort or pain do exist it follows that the disease has extended beyond the oesophageal walls into the posterior mediastinum. Hoarseness when present is usually due to paralysis of the left side of the larynx caused by involvement of the left recurrent nerve. Regurgitation, vomiting, loss of weight, weakness and pain are all symptoms of a late stage of the disease. Janeway, Jackson, Torek, Guisez,

Fig. 5. Gross specimen showing a large primary carcinoma of the oesophagus perforating into the right bronchus causing death by asphyxia. A large secondary growth 5 centimeters in diameter is seen several centimeters above the primary lesion. Microscopic section showed the lesion to be an epidermoid carcinoma, grade 3.

and many others interested in this work have made pleas for earlier diagnosis, but the early symptomatology is too vague to be of much help in this direction.

DIAGNOSIS

That the diagnosis of this disease may be completely missed has been shown by Cabot who reported 3,000 autopsies among which were 20 cases of carcinoma of the oesophagus. In 4 of these cases the diagnosis had not been made and in 3 it was merely suspected. This was a higher percentage of mistakes than occurred in any other disease. Oesophagoscopy is more popular now than it was in 1912 when Cabot made his report and undoubtedly the percentage of missed diagnoses has been reduced by that procedure.

Kussmaul in 1868 was the first to realize oesophagoscopy by passing a rigid straight

Fig. 6 Photomicrographs showing the three grades of squamous carcinoma found in the esophagus.

steel tube into the person of a professional sword swallower at Freiburg Mikulicz in 1881 showed that esophagoscopy was a feasible procedure but for the next 35 years there was steady opposition to the practice. Many cases of perforation and death were reported and this state of affairs continued up to comparatively recent years when the technique was made quite safe and the procedure became popular.

It must be emphasized that esophagoscopy is absolutely necessary for the making of an early and accurate diagnosis. Complicated apparatus, difficult roentgen ray technique and various opaque mixtures have been developed with the idea of making an early roentgen ray diagnosis possible but these have lost their popularity due to the more satisfactory esophagoscopic results.

The following diagnostic procedures are carried out at the Memorial Hospital. The patient's history is obtained and he is given a general physical examination. He is then referred to the Head and Neck Department where the oral cavity and larynx are carefully examined and blood drawn for a Wassermann test. Following this he is sent for fluoroscopy and barium swallowing and then X ray films of the esophagus and lungs are taken. With the data obtained on hand the pharynx is cocainized an esophagoscopy is done and a

biopsy obtained. Biopsies are now taken in all uncomplicated cases.

Fluoroscopy is essential for a complete examination because by this means we are able to observe the function of the esophagus. The procedure also determines the following points as regards cancer in this organ: size, shape, outline, and position of the lesion, size and shape of the lumen above and below the obstruction, the presence or absence of small marginal defects (Ernst) and fistulae and lung complications. This data is of utmost value in determining what form of treatment should be instituted. The esophagoscopist if possible should be present during the roentgen ray examination of his patient. By the use of a heavy thick opaque mixture and the taking of X ray films of the patient in several different positions it is possible to obtain a film such as that shown in Figure 11 which gives an accurate picture of the lesion—its position, shape, and size.

Of 203 cases in which the patients were examined roentgenologically positive X ray diagnoses of carcinoma were returned in 97 cases, obstruction in 47 cases, constriction or stricture in 21 cases, filling defect in 29 cases, irregularity in 8 cases, evidence of ulceration in 1 case. In no case was the lesion missed. Jackson reported a positive biopsy in each case diagnosed as cancer by his roentgenologist.

Fig. 7. Diagrammatic sketch illustrating the relative frequency with which the various organs and lymph node areas are involved in secondary deposits from carcinoma of the oesophagus. The diagram is based on 27 postmortem examinations. Of this number 13 cases showed no evidence of metastases.

TREATMENT

Treatment by radical surgery Surgical approach to either end of the oesophagus is readily accomplished and various successful procedures have been developed for radical removal of new growths in these locations. In the cervical region the affected portion of oesophagus is excised and a new tube is fashioned from a transverse skin flap. The operative mortality following this procedure is not high. Turner reports 9 cases operated upon with no mortality and a length of life after operation of 3 months, 4 months, 6 months, 1 year, 14 months and 18 months. At the time the report was made 2 patients were still

alive and well, 1 2 years and the other 9 years after operation. Turner found the length of life was only 4 months in the untreated cases.

The abdominal portion of the oesophagus may be approached by abdominal route and also by a posterior mediastinotomy (Lilienthal). The operative mortality and the end results of a series of cases treated by these procedures does not appear in the literature and one suspects that the results are not satisfactory.

Torek in 1913 reported the first successful case of resection of the thoracic portion of the oesophagus for carcinoma. He obtained a

TABLE III.—METHOD OF TREATMENT

The number of cases treated by the different methods and the average length of life is shown. Patients treated only by gastrostomy were those in which the general condition was too poor to permit palliative radiation.

		Cases	Average length of life after admission (in months)
External irradiation only	Moderate		5.33
	Intensive	8	3.39
Intra-oesophageal irradiation only	Radium in capsules		4.64
	Raden seeds		
External plus intra-oesophageal irradiation	Radium in capsules	1	.67
	Radium in capsules and radon seeds		6
	Raden seeds		
Gastrostomy only		12	3.3
Gastrostomy plus external irradiation		7	6.27

	Raden seeds		8
Gastrostomy plus external and intra-oesophageal irradiation	Radium in capsules	6	3.39
	Radium in capsules and radon seeds		5.5
	Raden seeds		
Total cases of non-specific treatment			3

cure. His patient died 13 years later of pneumonia without recurrence of her cancer. In a later communication Torek called attention to the difficulties of the operative treatment and outlined the various causes of failure but concluded that operation offers the only hope of cure. The operative mortality, he believes, can be lowered by careful selection of cases. Saint made a very systematic and impartial review of the surgery so far attempted for car-

cinoma of the oesophagus. He concluded that the anatomical structure and relationships of the oesophagus, the highly malignant nature of the disease, the frequency of metastases, and the danger of fatal postoperative shock and infection should lead to the use of palliative measures as a routine.

Treatment by irradiation. External irradiation by means of X ray and radium has in the past been given merely with the hope of retarding the tumor growth and perhaps lessening the severe pain often associated with the late stages of the disease. The dosage has been totally inadequate to cause complete regression. From a review of the anatomy and pathology of carcinoma of the oesophagus, it appears logical to expect more from roentgen radiation of these lesions. With this in mind we are at present using a method of accurately outlining on the skin surface four treatment portals so located that the beams of X ray will crossfire at the level of the tumor. The beam of radiation is so directed as to pass through the least possible amount of lung tissue. It has been found that 2,000 r may be given through each of four portals without blistering the skin or causing severe constitutional symptoms. This technique is being

Fig. 8. Chart showing the comparatively large number of Russians in the Memorial Hospital series.

Fig 9. Chart showing the comparative age distribution in carcinoma of the oesophagus. The women are represented by the solid black portions. The female sex tends to acquire carcinoma of the oesophagus at an earlier age than does the male

used in a series of cases and the results will be reported at a later date

Intra-oesophageal irradiation by means of radium in the form of capsules has been used by Guisez in a large number of cases. He reports temporary, but definite decrease in dysphagia in all his cases and his results are surprisingly good. He reports 270 patients treated with intra-oesophageal radium, 30 patients lived more than 18 months, 4 died of intercurrent affections without any evidence of cancer in the oesophagus, 1 was alive 10 years, 1 11 years, 1, 5 years, 4 4 years, 4 3 years and 12 more than 18 months without evidence of disease. In all these cases biopsies were positive. He uses radium tubes of Dominici arranged in tandem and held in a bougie by means of which the tubes are accurately placed in relation to the tumor. Two or three tubes with a total of 10 to 12 centigrams of radium bromide screened by 1.5 millimeters of platinum are used and inserted every 2 days for 10 to 12 hours. Five or six treatments are usually given. Of the cases which we have treated by intra-oesophageal irradiation none has lived long enough to encourage us to continue with this method.

The insertion of gold filtered radium emanation seeds directly into the tumor has given only indifferent results (Table III).

Intra-oesophageal manipulations. Bougienage and dilatation of the carcinomatous stricture has been given a trial at the Memorial Hospital. The deliberate tearing and stretching of a carcinomatous stricture with the resultant opening of new blood and lymph channels for dissemination of disease together with the danger of rupture of the oesophagus, haemorrhage and fatal sepsis have led us to limit the number of cases treated by this method. During the later stages of the disease it becomes impossible to dilate the lumen and a gastrostomy becomes necessary unless one elects to send the patient home to die slowly of starvation.

None of the cases in our series was intubated or treated by coagulation with the high frequency current. These methods are occasionally advocated in the literature.

Palliative treatment. Gastrostomy if done early in the course of the disease should have practically no operative mortality. If this procedure is carried out in every case regardless of the stage of the disease a certain num-

Fig. 6. Chart showing the number of cases of each age. The youngest patient in this series was a woman 35 years of age, and the eldest was a man of 80. More cases, male and female, acquired the disease during their sixtieth year than during any other similar period of time. The females are represented by the solid black.

ber of cases will die after operation but the causes of death will usually be due to perforation into the aorta with fatal hemorrhage, pneumonia from a broncho-oesophageal fistula (Fig. 12) mediastinitis etc. Such must be called postoperative deaths but they are in reality deaths due to the patient's disease. In most cases the operation is done under novocain infiltration and block anesthesia and is accomplished without shock to the patient who sits up in bed on return to the ward and is fed through his gastrostomy tube immediately. He is out of bed on the third day after operation and soon begins to gain weight. The dysphagia definitely decreases and the patient's morale improves with his strength. Our recent results with gastrostomy are very encouraging and these statistics together with a description of the operative technique have been published (Martin and Waston).

At Memorial Hospital palliation has been aimed at and gastrostomy is usually done unless contra indicated or refused by the patient. This procedure has been combined with external or intra-oesophageal irradiation and in some cases with both. Seventy-one patients having had gastrostomy and external

irradiation lived an average of 6.27 months after treatment. Twelve patients treated by moderate doses of external radiation lived an average of 5.33 months after treatment. Table III shows the number of patients treated by various methods and the results.

PROPHYLAXIS

We do not see cancer of the oesophagus in patients with sound healthy clean teeth. Oral sepsis is usually advanced or if the patient be edentulous, it is possible to obtain a history of preceding dental caries in most cases. It seems to be a frequent disease among the Russian poor who take very little care of their teeth. Prophylaxis should begin with care of the teeth. Alcohol hot fluids, excessive use of tobacco and spiced food should be eliminated. Slow and complete mastication of food would prevent oesophageal trauma. Patients with oesophageal spasm must be treated and the public educated to the possible seriousness of such trifling symptoms as a feeling of substernal pressure and temporary dysphagia.

PROGNOSIS

Carcinoma of the oesophagus is a rapidly fatal disease. The average length of life from

Fig. 11 Carcinoma of the oesophagus showing the detail which may be brought on by careful radiographic technique.

Fig. 12 Roentgenogram on admission showing a broncho-oesophageal fistula developing in a carcinoma of the oesophagus. This patient had a gastrostomy performed for feeding purposes and improved enough to return home in 2 weeks after operation.

the onset of symptoms in this series was $10\frac{1}{2}$ months and the average length of life after application to the hospital was 4.83 months in the 208 cases followed. The disease advances so swiftly when symptoms are present that a fatal termination occurs often before metastases are demonstrable at autopsy. The disease spreads by three methods direct extension lymphatic permeation and the blood stream. At one time it was thought that the small islands of new growth sometimes seen dotted about the mucous membrane some distance from the primary lesion were carcinoma implants. Since then it has been shown however that these were really upshots to the surface of permeated intramural lymphatic

vessels. Table IV gives the average length of life in the different groups.

Of the thousands of cases of carcinoma treated yearly there has been a salvage of not more than 10 cases. The lethal nature of the disease becomes increasingly important when we realize that from 3 to 4 per cent of all cancer deaths occur in patients with carcinoma of the oesophagus. The high mortality and the relative frequency of the disease make worth while the studying in detail of any large series of cases with the hope that some clue to an earlier diagnosis may be obtained or a more rational method of treatment suggested. A

TABLE IV—AVERAGE LENGTH OF LIFE IN EACH GROUP

Epidermoid carcinoma	Grade	Grade	Grade 3	Adenocarcinoma	Transitional cell
Cases with complete data		8	20	13	8
Average length of life from onset of symptoms (in months)	6.34	8.7	1	18.68	14.6
Average length of life after admission to hospital (in months)	8.60	4.16	4.8	7.73	8.7
Average length of life after operation (in months)	8.55	3.74	3.88	8	7

mortality of practically 100 per cent seems a hopeless situation and small recompense for the time and effort which has gone into the investigation of this disease. It seems wise to attempt a cure only in the very few favorable cases and to treat the remainder in a routine palliative fashion—possibly best by external irradiation combined with gastrostomy.

SUMMARY

1 Intimate knowledge of the anatomy and histology of the esophagus is essential to the understanding of the treatment problems of cancer in this organ.

2 The exact etiology of esophageal carcinoma is still obscure but definite predisposing and exciting factors are known and should be an aid in prophylaxis.

3 Cancer of the esophagus makes up between 3 and 10 per cent of all the carcinoma deaths.

4 The disease is most frequent in the lower third of the esophagus.

5 Of the 267 cases with positive biopsies 15 were grade 1 148 grade 2 39 grade 3 19 adenocarcinoma, 6 transitional cell carcinoma and in 40 cases the tissue was unsatisfactory for grading.

6 Adenocarcinomata of the esophagus are more slowly growing and give symptoms earlier than do the squamous cell lesions.

7 Of the cases coming to autopsy 48 per cent showed no evidence of metastases.

8 Bronchopneumonia was a cause of death in 48 per cent of the cases.

9 Radical surgery of the esophagus is indicated in a few early cases.

10 The routine treatment should be palliative.

11 Gastrostomy followed by external irradiation offers the most satisfactory palliation.

12 Prophylaxis should be stressed.

DIVERTICULUM OF THE URINARY BLADDER

AN ANALYSIS OF ONE HUNDRED CASES¹

ADOLPH A. KUTZMANN, A.B. M.D., F.A.C.S., LOS ANGELES, CALIFORNIA
 From the Urological Service of the Los Angeles General Hospital

THE status of bladder diverticulum has passed from a rare clinical entity to a common urologic diagnostic finding. It is a far cry since there appeared in all but 6 cases in the American literature and when other contemporary reports showed but 6 collected cases from the world's literature in which the sac had been excised. Prior to the present century the occurrence of diverticulum was usually found upon postmortem examination. The ready facility now of its clinical recognition is due to the progress achieved in cystoscopic and roentgen ray procedures in urologic diagnosis.

Diverticulum of the urinary bladder has led to some interesting anatomophysiological problems, chief of which have been etiology and anatomy. Various theories have been promulgated and according to these theories diverticula may be divided in four principal groups: (1) diverticula which are caused as a result of congenital and acquired factors; (2) diverticula congenital in origin; (3) diverticula of the acquired type; and (4) diverticula that may be either purely congenital or purely acquired.

Some observers maintain that diverticula are congenital and have based such an opinion on the fact that they occur in infants and young children. Others have contended that all diverticula are acquired since they are rarely found when urinary obstruction is absent. Most of the present day observers take a more logical intermediate viewpoint namely that diverticula may be the result of both congenital and acquired factors. They may exist from birth chiefly those in the fundus while the remainder are secondary to back pressure such affected bladders probably giving way at their points of congenital weakness. An analysis of the present series of cases leads the writer to the same conclusion since it was possible nearly always to demonstrate

some type of bladder neck or urethral obstruction.

Anatomically the walls of the diverticula are essentially composed of fibrotic and connective tissue fibers permeated with inflammatory elements. Some observers have reported the finding of occasional bundles of muscle fibers which when present are said to be widely scattered or interwoven with the fibrous tissue. There is no evidence of any layer formation similar to that found in the bladder wall proper. Usually all diverticula have a smooth glistening lining membrane unlike the bladder mucosa in appearance and showing histologically a flattened type of epithelium. This has not however been substantiated by some observers. Examination of the pathological material from the diverticulectomies in the present series of cases revealed that the diverticula were composed of fibrous tissue with chronic inflammation. A lining epithelial membrane was present in all and appeared histologically to be of a more flattened squamous type than that found in the bladder proper.

Clinically, diverticula of the bladder have presented many interesting facts. There is no distinctive symptomatic syndrome. This lack of symptoms makes their recognition by diagnostic procedures with the cystoscope and X ray one of importance. At times the presence of diverticula may not be discovered by these urological diagnostic procedures but may later be found at open operation. Significant factors, as situation in relation to position and drainage, size of the orifice and sac, number, exact nature of the etiological obstructing factor, type of urinary infection, must be carefully ascertained. Recognition of such complicating associated factors as calculus, carcinoma, leucoplakia and tuberculosis are of paramount importance if the condition is to be adequately remedied. Treatment in most cases has been the relieving of the ob-

structing factor. If the diverticulum is of the retention type urinary stasis occurs which usually leads to severe urinary infection with organisms of the urea splitting type as the streptococcus staphylococcus or *Bacillus proteus*. Such an infection may result in a very irritating ammoniacal urine and therefore such diverticula must also be treated either by resection of the entire sac or a plastic procedure to their orifices so as to insure proper drainage. The latter procedures are also usually applied to large diverticula.

There have been observed 100 cases of bladder diverticulosis in the Los Angeles General Hospital within the last 5 years and for that reason the following analyses and conclusions are detailed.

ANALYTICAL SUMMARY OF ONE HUNDRED CASES OF DIVERTICULA OF THE URINARY BLADDER

During the last 5 years there have been 5984 admissions to the urological service. Among these have been observed 100 cases of

diverticulosis. These cases have been divided into two groups: true diverticula and false or incipient diverticulosis. The basis for this division is upon the criteria that false or incipient diverticula are for the most part cellules or shallow wide mouthed depressions due to the protrusion outward of the epithelial lining between hypertrophied muscle bundles and are nearly always multiple and found throughout the bladder (Fig. 2), the true diverticula are more commonly single and larger in size, exhibiting a definite orifice having an anatomical sac like structure, and are usually situated in the region of the ureters (Fig. 1).

There were 72 of the true type and 28 of the false cases. This makes an incidence of 1.2 per cent or one in every 83 general urological admissions. Of the 72 true cases, 43 were found among 467 cases of benign hypertrophy of the prostate or an incidence of 9.1 per cent (1 in 10.8), 14 were among 83 bladder neck contractures and median bars—11.8 per cent (1 in 5.8), 3 were among 254 carcinomata of

the prostate—1.1 per cent (1 in 84) and 3 were among 21 urethral strictures necessitating operation (external urethrotomy)—14.2 per cent (3 in 21) (Table I). It is interesting to note

from these figures that the relative incidence is more common among bladder neck contractions, median bar and urethral strictures than in the presence of benign hypertrophy of the prostate.

An analysis of the symptoms shows that bladder diverticulum is not a distinct clinical syndrome (Table II). The incidence of various urinary disturbances presents a clinical picture similar to that of an obstructive uropathy in the lower urinary tract (bladder neck and urethra) with a complicating infection. Frequency in 53 cases, difficulty in 44 cases, nocturia in 40 cases, dysuria in 39 cases, dribbling in 27 cases and burning in 23 cases were the symptoms most frequently encountered. Twenty-one cases entered the hospital with complete retention. The outstanding characteristic of the symptomatology was the

long duration, some patients having had urinary disturbances, in a mild form, well on to 15 years.

A distribution of 97 cases in men and 3 in women emphasizes the fact that diverticulum of the bladder is a disease of the male urinary bladder. Most cases were found in later life 91 per cent occurring after the age of 50 years, the largest number in any one period was 42 and occurred in the seventh decade of life. No infants nor children were encountered (Table III). This distribution can be assumed

as supporting the "acquired theory," showing that it is necessary first that an obstructive process develop.

True diverticula of the bladder tend toward singularity for instance, 38 cases had 1 diverticulum 21 cases had 2 and 12 cases had 3 or 4. This distribution of the diverticula was essentially in the ureteral region as evidenced by the fact that in 24 cases the opening was in the right ureteral region in 13 in the left ureteral region in 22 the openings were bilateral and in 7 in the posterior and fundal

Fig 7A, left. Cystogram illustrating an opening in the fundus of the bladder caused by a perforating intestinal carcinoma. Such a picture may be confused with diverticulum.

areas (Table IV). A total of 65 of the 72 true cases (90 per cent) were found in the region of the ureters and this fact can be taken as further confirmatory evidence that the weakest points in the bladder musculature are in the vicinity of the ureteral orifices or that there may remain from a faulty embryological development small patent ureteral buds which in later life develop into diverticula—a fact that must be considered in some cases in women in whom examination fails to disclose any obstructing factor. This may be explained by the embryological development of the ureter

as it buds off the cloaca or by the fact that there can occur an absence of longitudinal muscle at these points. It may therefore be considered that a bladder wall must possess congenitally weak areas as the site of election for diverticulum formation but that a diverticulum may never occur in the male unless there is an obstructive factor at either the

Figs. 9A and B. Contrast cystograms showing two retraction diverticula on the posterior wall of the bladder.

Figs. 9C and D. Contrast cystograms several months after diverticulectomy demonstrating a good anatomical result.

An analysis of the etiological conditions showed that prostatism and urethral stricture especially the former were the dominant productive factors in 90 male patients. There were 64 cases of benign hypertrophy with 43 cases of true diverticula, 18 cases of bladder neck contracture and median bar formation with 14 cases of true diverticula, 5 cases of prostatic carcinoma with 3 true cases, 3 cases of urethral stricture with true diverticula, the remainder were individual cases of urethral caruncle (female), hypertrophied trigone (female), bladder carcinoma, cord injury, spastic paraplegia, and 3 cases (1 female) not stated (Table V).

In 30 cases there were associated conditions. Sixteen exhibited urinary calculi distributed as follows: 12 with vesical calculi, 5 of which were within the diverticulum, 3 with renal calculi, and 1 with prostatic calculi. Seven patients had lues, 2 had carcinoma of the bladder, and 1 each had an epithelioma of the kidney pelvis, adenocarcinoma of the rectum, epithelioma of the ear, a papillary carcinoma of the intestine invading the bladder, and diabetes (Table VI). In none of the cases of diverticula was there found an associated neoplasm, leucoplakia, or tuberculosis.

Treatment was directed chiefly toward the etiological condition and secondarily to the

Figs. 10A and B. Contrast cystograms demonstrating a large retention diverticulum in the right wall of the bladder. There are several smaller diverticula on the left wall but these drain well.

Figs. 10C and D. Contrast cystograms 14 months after treatment with the Percy cautery to the diverticulum and its orifice. Although there has been a slight change in actual size, satisfactory drainage has been achieved.

diverticulum if it was of the retention or large type. Upon this basis the etiological condition was corrected or treated palliatively in 75 cases and the diverticulum was treated directly in 17 cases. In 44 cases prostatectomy was done (2 in one stage, 38 in two stages and 4 by the perineal route), in 15 cases bladder neck punch operations were done (11 open and 4 closed), in 15 cystotomy was done and in 1 a prostatic resection with the high frequency loop. In the 17 cases in which the diverticulum was treated directly

the following operations were done: divertic ulectomy, 8 cases; the Squier operation, 3 cases; orifices punched out, 3 cases; Percy cautery, 3 cases (Table VII).

A study of the follow up letters has shown that our method of treatment was adequate in the majority of operative cases. Most cases showed improvement as evidenced by a marked diminution in symptoms and urinary infection, disappearance of residual urine and distinct gain in general health. Follow up cysto-urographic studies of such treated cases

as could be reached who had had a prostatectomy or had had in addition some plastic work on the diverticulum orifice revealed for the most part very little change in the size of the diverticulum proper. However the important factor—drainage—had been achieved. An excellent anatomical result was obtained in the several patients who had had a diverticulectomy. From our data it may be inferred that a minimum amount of attention may be paid to the diverticulum proper but that it is most important to remove all etiological obstructing factors and to institute thorough drainage. If such has been achieved and there are no diverticula of the retention type present the patient will be greatly benefited.

Unless the indications be definite such as retention, poor drainage, marked infection, small orifices, diverticula for the most part can be ignored following the remedying of the bladder neck obstruction. Attempts to treat surgically some types of diverticula, as for instance those situated in the subtrigonal and ureteral regions, may lead to much additional technical difficulty, often producing surgical shock and even death.

CONCLUSIONS

1. Diverticulum of the urinary bladder is a disease which affects the male chiefly and occurs for the most part in later life during the

prostatic age. It is nearly always associated with an obstructive condition as prostatism or urethral stricture.

2. The incidence of diverticulum is as follows in the urologic cases in general: 1.2 per cent in benign hypertrophies, 9.1 per cent in contractures and median bar obstruction, 16.8 per cent in urethral strictures necessitating operation, 14.3 per cent and in carcinoma of the prostate 1.1 per cent. No definite clinical symptomatology is noted except possibly if a lower urinary tract obstruction with infection is present there is an accentuation of the characteristic symptoms of the associated condition.

3. Diverticulum of the urinary bladder is the result of both congenital and acquired anatomical factors.

4. Anatomically it was found in the present series that the walls of the diverticulum showed fibrous tissue with permeation of chronic inflammatory elements. The diverticula were lined with smooth, glistening membrane histologically the flattened type of epithelium.

5. Diverticulum of the urinary bladder is treated most satisfactorily by the correction of the obstructing factors, only such diverticula being individually treated as may be of the retention type or of a large size. This method of procedure will give gratifying relief from symptoms that have been intense and of long duration.

HYPERTROPHIC INTESTINAL TUBERCULOSIS¹

A. A. DAVIS CH M (VICT) FRCS (ENG.) MANCHESTER ENGLAND

Surgical Registrar Manchester Royal Infirmary

THE present paper is based upon a review of twenty nine cases of hypertrophic tuberculosis of the intestine treated in the Surgical units of the Manchester Royal Infirmary during the past ten years. The number of cases recorded is small the disease being a comparatively rare one (during the same period and in the same institution the number of patients admitted suffering from intestinal carcinoma was 1123). The results of surgical intervention however particularly when of a conservative nature have been so generally successful in this group of cases that it is suggested that a statistical consideration of the etiology and treatment of the disease based upon them might be of value.

It is perhaps advisable to indicate at the outset that consideration is limited entirely to those cases corresponding to Type 4 of the so called 'French' classification of intestinal tuberculosis. This which is purely a pathological one enumerates the following varieties (1) the ulcerating type or tuberculous enteritis (2) the stenosing type (3) the enteropertoneal type and (4) the hypertrophic type.

Types 1 and 2 being invariably secondary to phthisis in adults and forming the bulk of intestinal cases in children constitute the overwhelming majority of all cases of intestinal tuberculosis. The remaining types are comparatively rare but as one of these the last is the only variety amenable to surgical treatment—with the exception of those secondary cases in which perforation or acute obstruction demand urgent relief—it is only this type which is seen with any degree of frequency by the surgeon.² This is illustrated by the fact that of the 35 cases of all types of intestinal tuberculosis treated in the surgical wards of the Royal Infirmary during the period under review 29 were of the true hypertrophic variety.

A comparative analysis of these cases follows.

ETIOLOGY

Situation The situation of the focus of disease is indicated in Table I.

TABLE I—DISTRIBUTION OF THE LESIONS

	Cases
Ileocaecal region	22
Sigmoid colon	3
Hepatic flexure	1
Ascending colon	1
Appendix	1
Jejunum	1
Total	29

These figures correspond fairly closely to the majority of published surgical data. Of Mummery's list of 100 collected cases of hyperplastic tuberculosis affecting the colon 87 involved the caecal region 6 were confined to the sigmoid while the whole or a large part of the colon was invaded in the remaining 7. Anderson and Munro reporting 9 similar cases state that 6 were of the caecal type 2 were situated in the transverse colon while 1 was of the diffuse type involving the ascending and transverse limbs. No cases involving the transverse colon occurred in the Infirmary series. It is a rare lesion only 2 of 43 cases of hyperplastic intestinal tuberculosis reported by Caird being affected in this region. Similarly I have been unable to find in our series an example of the peculiar 'gas-pipe' colon where the whole colon is the seat of a generalized tuberculous thickening but this is scarcely surprising as the type is extremely rare the only published cases being single ones reported by Braddon, Lartigue, Elliott and Mummery.

Age incidence The average age of the patients was 30 years the youngest being 9 the oldest 69 years.

These figures correspond closely to similar published statistics. The average age in Mummery's 80 cases was 32 years the oldest patient being 78 years and the youngest 7. Erdman's 6 cases gave an average age of 30.

¹ The extensive operative procedures advocated by Archibald, of Montreal, for uncomplicated secondary tuberculous enteritis have never been widely adopted, in spite of the good results claimed by this author.

Fig. 1. Hypertrophic ileocecal tuberculosis. Case No. 20630. } G. male aged 63 years. Symptoms of chronic intestinal obstruction for 6 months, with a large fixed tumor in the right iliac fossa. Operation, November 20, 1929, ileotransverse colostomy (tumor irremovable). Examined November 2, 1931 and found fit and well. He has gained one stone in weight, has no intestinal symptoms. Tumor is palpable. (Postoperative barium enema X-ray refused. X-ray by Drs. Paterson, Twining, and Gray.)

years. Very similar figures are reported by Nikolyski, Mueller, Shiota and Kuettner. It is of interest to note that this average age of 30 years is also the average age of several large series of phthisical patients.

Sex incidence. Twenty-one of the cases were females and 8 males.

This sex incidence is somewhat different from that usually accepted namely that the sexes are affected with equal frequency. This ratio is illustrated by the list of published figures quoted by Mummery (Table II).

TABLE II.—SEX INCIDENCE

	Cases	Males	Females
Mummery	80	47	33
Conrath	77	36	41
Bernay	71	40	3

Mueller actually reverses the order by stating that males are affected more than females in the proportion of 3 to 2. The discrepancy, one supposes, is due more to the (comparatively) small number of cases reviewed than to any etiological factor.

Incidence of tuberculosis elsewhere. Table III is self explanatory.

TABLE III.—INCIDENCE OF CONCURRENT TUBERCULOUS LESIONS

	Cases
Phthisis	3
Jejunal ulcer	1
Hyperplastic tuberculosis of rectum	1
Tuberculous arthritis of elbow joint	—
Tuberculous ischiofemoral abscess and tuberculous structure of ileum	6
Percentage	20

It will be seen that only 2 of the patients suffered from phthisis—(one may add in parenthesis that now both these patients are free from active disease)—while 3 others had coincident tuberculosis of some part of the gastrointestinal tract. These findings are in accord with the generally accepted view that the disease is not usually associated with tuberculosis elsewhere except in a small though definite proportion of cases. It is interesting to note that the percentage of cases free from other tuberculous disease in Mummery's series, namely 24 per cent, is very close to the figure of 20 per cent in the Infirmary group. (Four of Erdman's 6 cases had quiescent phthisis, but it would appear unjustifiable to accept percentages based on such a small figure.)

The question of primary or secondary infection. These results throw little light on the interminable discussion as to whether hypertrophic intestinal tuberculosis is truly a primary or a secondary disease. Cumston believes that it is almost always primary. Hemmeter that it is usually secondary to phthisis and all variations of opinion between these two extremes have been registered by various authorities. A variety of causes would appear to account for these differences. In the first place it is probable that too much importance has been attached to the 2 classical cases of Lartigau and Beck in which each observer failed to find any evidence of tuberculosis elsewhere in spite of a most exhaustive and minute postmortem examination. It is surely an exaggeration to make these isolated findings the basis of a contention that all the cases are primary in origin. Second assumptions based on the review of a small number of cases, with consequent misuse of the percentage system, must inevitably lead to many fallacies. In the third place most of the

larger series include in the figure all the widely varying types of intestinal tuberculosis in spite of the fact that (at least in adults) the very common ulcerative type is almost invariably secondary. In this connection some figures quoted by Lawrason Brown and Sampson are of interest. On postmortem examination Heller found primary intestinal tuberculosis in 16 of 107 cases (in children in whom the incidence of the primary type is admittedly most common). Bonome in 126 cases out of 769 cases of tuberculosis. Biedert in 16 out of 3104 cases of tuberculosis, Bovard in 150 out of 1481 tuberculous cases, while Gant in a collected series of 22 725 autopsies, found primary intestinal tuberculosis present in 7.22 per cent. Hartmann goes so far as to state that 85 per cent of all cases of tuberculosis of the intestine in adults is of the hyperplastic type.

Careful assessment of most of the published figures of postmortem clinical and X-ray findings suggest that roughly 70 per cent of all cases of hypertrophic intestinal tuberculosis are truly primary in origin. It will be noticed that both in Mummery's and the Royal Infirmary series this figure is closely approximated.

Fig. 1. Hypertrophic tuberculosis of hepatic flexure. Case No. S 833/24. J. W. male aged 45 years. Three months history of subacute intestinal obstruction. Loss of weight very marked. Large fixed tumor in right hypochondrium. Operation, September 22 1924 ascending transverse colocolostomy (tumor irremovable). Examined November 12, 1931 and found to be in excellent health. Weight steady. No intestinal symptoms. (Postoperative barium-enzyme X-ray refused) (X-ray by Drs. Paterson, Twining and Gray)

SYMPTOMS

The duration of symptoms, the incidence of individual symptoms and the types of symptom complex are summarized in the Tables IV, V, VI.

It will be noticed that of the various symptom complexes exhibited the commonest is that of a subacute intestinal obstruction with intermittent attacks of intestinal colic, a definite tendency to constipation with very occasional attacks of diarrhoea, the whole extending over a fairly lengthy period of a year or more. Alternating constipation and diarrhoea, the presence of blood or slime in the stools or diarrhoea alone are only very occasional symptoms but a striking feature is the presence in 65 per cent of the cases of a palpable abdominal tumor noticed in more than half that number, by the patient himself. In one case acute intestinal obstruction, a complication of comparative rarity supervened. The

communication to Masson. He mentions 7 cases of ileocecal tuberculosis which were so improved by a first stage lateral anastomosis that further treatment by resection was unnecessary.

The possibility of carcinoma supervening is probably much exaggerated, though there is no doubt that it does exist as two cases recorded by Herzog testify but it is so rare that it may be completely discounted as an argument for resection.

PRIMARY APPENDICULAR TUBERCULOSIS

One case confined to the vermiform appendix occurred in our series. The symptoms were those of typical recurrent appendicitis culminating in an acute attack, for which the appendix was removed and only shown on microscopic examination to be tuberculous. The other organs were apparently normal. The patient unfortunately is untraceable.

This subject has been exhaustively reviewed by Warwick, who quotes Scott's collected figures concerning the frequency with which tubercle is encountered in the routine examination of all appendices removed for other conditions, principally acute appendicitis. The list shown in Table X is modified from her paper.

In a series of collected English cases, Lock

wood found the percentage affected to be 1. Analysis of the Mayo Clinic figures show a considerable decline in the incidence during the last 2 decades, a change ascribed by W. J. Mayo to the almost universal adoption in America of the clean milk supply.

HYPERTROPHIC TUBERCULOSIS OF THE SMALL INTESTINE

An example of hypertrophic tuberculosis involving the jejunum 18 inches from the duodenojejunal flexure, occurred in our series. This is an extremely rare condition, so uncommon that I have been able to find no more than 8 cases recorded in the literature. (Masson and McIndoe, Cunningham and Sniersen, Garvin, Counsellor, Lartigan.) The patient, a man aged 51, gave a 6 weeks' history of sub-acute intestinal obstruction with severe colic like pain and vomiting. Examination revealed a mass in the right iliac fossa, diagnosed at operation as a carcinoma of the upper jejunum. The tumor was excised with some inches of bowel on either side and end-to-end jejunostomy was performed. Subsequent microscopic examination gave the true diagnosis. Two and a half years later the patient states that he is in perfect health.

CONCLUSION

The subject of this inquiry was suggested by an observation of W. J. Mayo's (quoted) commenting on the freedom from symptoms enjoyed by several patients, following a first stage short-circuiting operation for ileocecal tuberculosis. Investigation into the after history of twelve similar cases similarly treated has shown an identical result, with complete freedom from symptoms, disappearance of the tumor when present, and rapid improvement in general health, in all the cases, at intervals varying from 1 to 4 years after operation.

It is suggested therefore in view of these and similar published statistics that the view generally held that complete eradication is a *sine qua non* in the effective treatment of this disease is fallacious, and that focal excision in view of the mortality implicated, is an unnecessary procedure, except in picked, suitable cases.

I am indebted to the honorary surgeons and assistant surgeons of the Manchester Royal Infirmary for permission to investigate their cases, and particularly to Professor E. D. Telford, for his kind help and advice.

THE EXCRETION OF OVARY STIMULATING HORMONE IN THE URINE DURING PREGNANCY

ITS RELATION TO URINARY OUTPUT

DOUGLAS P. MURPHY M.D., F.A.C.S., PHILADELPHIA

From the Gynecologic Hospital, Institute of Gynecologic Research, School of Medicine, University of Pennsylvania

THIS report concerns the amount of ovary stimulating hormone which is excreted in the urine during pregnancy and the effect of alteration in the output of urine upon the rate of excretion of the hormone. No report was found in the literature which recorded the measurement of the hormone in the urine, by the use of the rabbit test of Friedman¹ and none occurred which dealt with the relation between the output of urine and the excretion of hormone as measured by any method. For these reasons the present study was undertaken.

EXPERIMENT

The amount of urine passed in 24 hours by a series of 24 pregnant women was measured and the hormone content determined. A correlation between the sizes of the specimens and the amounts of hormone which they contained forms the basis for the report.

In order to secure accurately collected specimens passed by normal pregnant women living under uniform physical conditions an attempt was made to hospitalize an adequate number of such individuals. Failing to secure a sufficient number of normal subjects, it was found necessary to utilize other hospitalized patients, who exhibited mild or moderately severe complications of pregnancy (Table I). All but 2 of the 24 patients were in the middle or last third of gestation (Table III) and all but one were confined to bed on the day that their urine was being collected.

First, a 24 hour specimen was collected from each of the 24 individuals, when on a normal fluid intake measurement of the hormone in these specimens supplied data on the limits of its excretion. On the following day 6 of the 24 patients gave a second 24 hour specimen, which was much larger than the

first one due to a forced ingestion of fluids. A comparison of these specimens with the first ones, formed the basis for observations on the influence of urine output on hormone excretion.

Preparation of urine. Each 24 hour specimen of urine was measured, and a sample retained for analysis. A 30 cubic centimeter portion was chilled, acidulated slightly with acetic acid if alkaline, and filtered. It was then well shaken with five volumes of absolute alcohol and the mixture was permitted to stand in the ice box over night. The material was centrifugated, and the supernatant liquid poured off the residue was air dried and put into normal salt solution the latter equal in amount to one half of the original volume of chilled urine. This extract was employed as the source for the hormone.

Preparation of animals. Adult female rabbits in the estrous stage, were used for all tests. In order to assure a suitable degree of heat, each animal was permitted to cast a litter being caged alone from the date of the last successful mating until the end of the experiment. The litter was removed the day of birth and the animal used for test shortly thereafter.

Hormone unit and method of measurement. The amount of hormone is expressed in rabbit units (Rb U). A rabbit unit is defined as that quantity of hormone present in the smallest amount of urine which, on intravenous injection into an estrous rabbit, will be followed by rupture of at least one follicle. In order to discover this amount of urine a series of rabbits, one animal a day received graduated intravenous injections of the urine extract until the maximum non-effective and minimum effective doses were determined. An arbitrary dose was given to the first animal of each series. If follicular rupture was not observed at operation or at necropsy 20 to 24 hours

TABLE I—HORMONE EXCRETION AND HEALTH

Recording (1) the amount of ovary stimulating hormone excreted in 24 hours by 24 pregnant women living under similar controlled physical conditions, and (2) the relation of the amount of hormone to the health of the patients. Note the large number of specimens (14 in 24) which contained less than 2,000 rabbit units of hormone and the fact that the normal patients, and most of the unhealthy ones excreted less than 7,000 rabbit units of hormone.

Thom- as's Rb.U.	Urine speci- mens No.	Health						
		Normal	Mild tox- emia	Threat- ened abor- tion	Py- emia	Di- abetes	Car- diac dis- ease	Un- der- treated

Total	24	8	8	4	3	3	2	1

later, the next animal received twice the preceding dose. If the first dose was effective the following dose was reduced to one half of the former one. This dosage ratio was employed in all cases, except where amounts of extract exceeding 1 cubic centimeter were necessary. Here the increase of dosage was sometimes less than twice the preceding one. The amount of urine containing 1 rabbit unit is defined as that quantity midway between the maximum and minimum doses described. With this amount of urine determined, the hormone content of the 24 hour specimen was computed.

RESULTS

The amount of hormone excreted in 24 hours
The amount of hormone excreted in 24 hours by 24 pregnant women living under controlled physical conditions and on a normal fluid intake, is recorded in Table I. Though the upper limit of excretion of hormone was in the neighborhood of 14,000 rabbit units more

TABLE II—DURATION OF PREGNANCY WHEN URINE WAS MEASURED

	B	2150	1300
6	A	780	195
	B	1400	121

than 58 per cent of the patients excreted less than 2,000 rabbit units.

Since most of the patients suffered from complications of pregnancy, and because little is known regarding the relation between them and the excretion of the hormone, their relation is shown in Table I. The normal patients and most of the unhealthy ones excreted less than 7,000 rabbit units.

Three of the pathological conditions are of interest—toxemia and abortion, because they are peculiar to pregnancy, and diabetes mellitus, because, in the specimens from the diabetic patients an unusually large amount of hormone was present (Table I). Since the amounts of hormone in the first two conditions were not unusual, it appears unlikely that such complicating conditions influence the rate of excretion of the hormone. Whether the presence of diabetes mellitus is related directly to the large amount of hormone, which 2 patients having this disease excreted, requires further investigation.

The relation of output of urine to excretion of hormone Two 24 hour samples of urine passed on succeeding days were collected from 6 individuals. In each instance the first sample was the smaller and resulted from a normal intake of fluid the second larger specimen followed a forced ingestion of fluid. In each case the 2 specimens varied approximately 100 per cent or more in size (Table III) whereas the amounts of hormone which each contained were about equal. From a comparison of the figures in this table, it appears that the excretion of hormone by the same individual on succeeding days does not increase with increase in the output of urine, but remains constant. In fact, from a study of these cases, and of 4 which are not recorded, an increase in the output of urine not only was not associated with an increase in the amount of hormone which was excreted but, if any relation between the two does exist an increased output of urine was usually associated with a decrease in the excretion of hormone the latter result however is believed to be more apparent than real.

Deductions The number of observations in this study is small and the patients who supplied urine specimens were not all healthy, nor were they in the same state of pregnancy. Also the number of animals for use was limited. Nevertheless the results seem to be significant.

It is apparent that the excretion of the hormone is independent of the output of urine that an increase in the latter has no tendency to wash an additional amount of hormone out of the body. In fact, the reverse may be true. This latter point needs further investigation.

Because the excretion of hormone is constant and the output of urine normally is variable, it follows that the concentration of hormone must vary from sample to sample of urine. Consequently the excretion of hormone cannot be expressed accurately if at all, in terms of urine output. It is evident therefore that the amount of hormone which is excreted must be measured directly and should represent the amount passed in a suitable period of time in order not to reflect marked alteration upon it by changed physical

conditions. For such a measurement, the 24 hour specimen seems most suitable.

The present method of measuring the amount of hormone in the urine is more accurate than other biological ones¹ but like them, possesses too many disadvantages to make it suitable for clinical purposes, though it will continue to have value as a research method. The expense of maintaining a large colony of animals and the time consumed in securing an adequate number of animals in a suitable degree of heat are two of the chief disadvantages of such a procedure. These combined with death of animals shortly after injection and the wide variation in the amounts of hormone in the different specimens of urine, which necessitated many unsuccessful measurements before the desired determinations were secured, greatly prolonged the period of the present study.

In spite of these difficulties, additional quantitative estimations of the hormone either in the urine or blood or in both should be carried out, and the normal limits be clearly established, after which the amount in pathological states should be estimated. By such studies light may be thrown on the causes of some of the pathological conditions peculiar to pregnancy as well as upon the influence of these diseases on production and excretion of hormone.

SUMMARY AND CONCLUSIONS

1 The amount of ovary stimulating hormone (expressed in rabbit units) in 30 24 hour specimens of urine of 24 pregnant women is recorded.

2 Some patients were normal others exhibited mild complications of pregnancy the majority were in the last third of gestation when their urine was collected.

3 The amount of hormone excreted in 24 hours varied from less than 100 to more than 12 000 rabbit units the majority of patients voided less than 2,000 rabbit units.

4 The excretion of hormone by the same individual from day to day was relatively constant and was independent of the output of urine.

5 From these observations, it is concluded that

Idem. Personal communication.

a. Variation in the output of urine has no significant influence upon the amount of ovary stimulating hormone which is excreted

b. Estimation of the rate of excretion of ovary stimulating hormone, should be based upon measurement of the hormone in the

urine that is passed in a 24 hour period, and not upon the amount in a smaller sample of urine

The author is greatly indebted to Dr M. H. Friedman for suggestions and continued assistance throughout the period of investigation.

PROFOUND BLOOD PRESSURE FALL WITH BRADYCARDIA

A NORMAL PULSE RATE IN SURGICAL PROCEDURES¹

HUBERTA M. LIVINGSTONE, M.D. S. ELIZABETH McFETRIDGE, M.D., AND ROBBIE BRUNNFR, M.D.
Chicago

THE pulse is an important factor in determining the general condition of a patient undergoing a surgical procedure. Frequently the person delegated to observe changes in a patient is a nurse, a medical student, or an occasional practitioner whose interest is primarily in the operation. From observation, it appears that the pulse rate as an index of threatened collapse has frequently been overemphasized and that careful observation is not made of changes in the quality of the pulse. Macleod (1920) speaks of the pulse being rapid during surgical shock. Howell (1927) and Orr (1928) state that the low blood pressure that is characteristic of the condition of shock is associated with a very rapid rate of heart beat. Our data indicates that the pulse is not necessarily rapid during the condition of so called "surgical shock."

Many authors including Cannon (1923), agree that a state of so called "shock" may be said to exist when the systolic pressure falls to, and remains as low as 80 millimeters of mercury. Since the use of the sphygmomanometer during surgical procedures has not, as yet, become widely employed, a proper interpretation of the pulse is even more important.

Observations including blood pressure and pulse changes have been made on 268 cases that presented during operation a systolic fall to 80 millimeters of mercury or less. The age incidence was fairly evenly distributed from 1 to 70 years. Three cases were over 70 years of age, 147 cases were male and 121 were female. Novocain, ethylene-oxygen, ethylene-oxygen

ether mixtures, ether, nitrous-oxygen gas, cocaine, and spinal anesthesia were the anesthetics employed, the last three agents being in the minority. A total of 4,410 operations are included in this series, 2,068 of which were major surgical procedures and 73 were double majors (operations lasting over 3.5 hours). Surgical procedures varied from minor operations as tonsillectomies to major intra abdominal and brain surgery.

In our series of 268 cases presenting a blood pressure below 80 millimeters mercury, 50 or 18.5 per cent did not exhibit a pulse rate above 100 per minute, 49 or 18.1 per cent, did not have a pulse rate above 120 per minute. In several cases the pulse did not become very compressible, weak and thready until some time after the blood pressure had reached an alarming level. The greatest age incidence of those not having a pulse rate above 100 per minute, but a low blood pressure, was from 30 to 70 years of age. Of the total cases studied 57 did not have a blood pressure below 80 millimeters of mercury but had a rapid pulse rate (above 120 per minute).

In a series of 12 anesthetized dogs in which death was brought about by hemorrhage one dog exhibited no increase in pulse rate, while two had an increase not to exceed 20 per minute (Fig. 1 and Table I). Dogs normally have an increased pulse rate associated with etherization. Following anesthetization, the 12 dogs observed had a minimum pulse rate of 170.

The early and correct interpretation of collapse during operation, and the resultant early

Fig. 1

administration of stimulants and intravenous normal salt Ringer's solution blood transfusion etc play an important rôle in the post operative course. A survey of some of the surgical services during a specific period including a few case reports may demonstrate the importance of observing blood pressure and pulse quality changes rather than changes in pulse rate.

Table II presents the neurosurgical operations. Of the 108 intracranial cases 74 exhibited a systolic blood pressure of 80 or less. Nine or 12 per cent of these did not have a pulse rate above 120 per minute. Of the 83 encephalograms 9 had a systolic pressure of 80 or less. It is of interest to note that all of these 9 cases did not have a pulse rate above 100 per minute. Sixteen of the 31 spinal cord operations had a marked fall in blood pressure associated in 7 cases with a slow pulse rate. The following case report illustrates this group.

No. 7395. A woman 70 years of age, entered the hospital on February 2, 1930, complaining that she had had pain across her back and down her legs for 9 months. Physical examination revealed a large well preserved individual weighing 48.4 kilograms. The blood pressure was 170/105 although the heart sounds were regular in force and rhythm and without murmurs. A roentgenogram revealed a heart 23 per cent oversize with calcification of the abdominal

aorta. The lungs were clear although tuberculous glands were excised from the neck in July 1929. Blood examination revealed red blood cells, 4,800,000 hemoglobin 86 per cent white blood cells, 9,500 Wassermann and Kahn tests were negative. There was a considerable quantity of albumin in the urine. A pre-operative diagnosis of cord tumor was made.

On March 4, 1930, a laminectomy was performed. Ethylene-oxygen induction was followed by a 4½ ounce ether anesthesia. Ether vapor was administered intermittently because of a narrow anesthetic margin and a tendency to cyanosis. There was a thick mucous discharge from the upper respiratory tract which was removed with suction. During the last 40 minutes of the 1 hour operation, the blood pressure was 80 millimeters of mercury or less.

Fig. 2.

systolic (Fig. 2). The pulse throughout remained slow and regular varying from 52 to 72 per minute. This patient required intensive intravenous therapy immediately after operation to bring the blood pressure and pulse quality back to a normal level. On March 8, 1930, the urine was normal and remained so throughout her stay in the hospital. She was discharged on May 23, 1930.

In 199 major upper abdominal operations, 31 or 15.5 per cent, exhibited a blood pressure below 80 systolic. Of these 8 or 25.6 per cent did not have a pulse rate above 100 per minute while 12 or 38.4 per cent did not have a pulse rate above 120 per minute. Of the 199 cases, 7 or 3.5 per cent did not have a blood pressure below 80 systolic, but had a rapid pulse (above 120 per minute). The marked blood pressure fall in this group usually occurred when the peritoneum was opened, or during traction or irritation of the upper abdominal viscera, especially in the liver or diaphragmatic area. This effect is in accordance with some phases of the work of Carlson and Luckhardt (1921) in frogs, and Scott and Ivy (1932) in frogs and dogs. Recovery usually occurred with lessening of the traction or trauma, or at least with peritoneal closure. Contrary to the observations of Crile (1903), who reports that the fall in blood pressure with upper abdominal manipulation is associated with a rapid pulse, we

found that the pulse rate usually remains low or even falls below normal. The following case report demonstrates this observation.

No. 36686. A housewife, aged 57 years, entered the University of Chicago Clinics on April 10, 1931, because of itching for 8 years, loss of weight for 6 months, diarrhea for 2 months, pain in the abdomen for 4 weeks, and jaundice for 1 month.

Physical examination revealed a well developed short, obese woman weighing 85.8 kilograms and 145 centimeters in height. The heart was normal and the blood pressure was 136/73. The lungs presented slight decreased resonance at the right apex. Enlarged tonsils, extensive varicosities of the legs, a femoral hernia, as well as an apparent non-tender mass in the right upper quadrant were present. The sclera were yellow. Blood examination revealed red blood cells, 5,160,000; hemoglobin 90 per cent; white blood cells, 6,100. Wassermann, Kahn, and urine examination were negative. The pre-operative diagnosis was chronic cholecystitis and cholelithiasis.

On June 2, 1931, a cholecystectomy was performed under ether anesthesia following ethylene-oxygen induction. Eight ounces, open drop ether was administered. The anesthetic lasted 2 hours, during the last 1 hour and 35 minutes of which the blood pressure was below 80 systolic, although the pulse rate never exceeded 108 per minute (Fig. 3). The patient received 1 cubic centimeter of ephedrine (hypodermically) during operation and 2 cubic centimeters caffeine sodium benzoate (hypodermically) at the close of operation. She was hyperventilated for a short period with carbon dioxide 10 per cent oxygen 90 per cent before leaving the operating room.

Fig. 3.

Fig. 4

The patient was returned to her room in only fair condition. The skin was warm and moist and the color was fair but the pulse was very weak, although the rate was 60 per minute. Ringer's solution, 1500 cubic centimeters was administered by hypodermoclysis, the pulse rate increased from 96 to 118 per minute, and the blood pressure rose to 100/60. The pulse also became stronger and of better quality.

Eight hours later 1500 cubic centimeters of Ringer's solution was administered by hypodermoclysis. There was a gradual fall in blood pressure until 5 hours later it was 84/60 and the pulse was 100 per minute and weak in quality. Adrenalin, 1 cubic centimeter, was administered hypodermically and the patient's condition improved. At 1 p.m. the follow-

ing day the blood pressure was 86/64 and pulse rate 120, so 1500 cubic centimeters of Ringer's solution was again administered by hypodermoclysis. At 4 p.m. although the blood pressure was 98/54, the pulse was weak and thready and the rate had increased to 144 per minute. A 300 cubic centimeter blood transfusion was given. At 6:30 the patient's condition was considered only fair although the blood pressure was 94/68 and the pulse 116 per minute. One week later the patient was feeling very well, but because of some loss of blood around the cigarette drain and from the center of the wound she was given 500 cubic centimeters blood and 200 cubic centimeters normal salt intravenously. The blood pressure was now 103/65 and the patient made an uneventful recovery.

Fig. 5.

On July 16 1931, patient successfully underwent an operation under local anesthesia for the repair of the femoral hernia. Except for a pulse that was irregular in quality and rate the operation was uneventful. She was discharged in good condition on July 30, 1931.

De Lee (1928) states that in cases of ruptured ectopic pregnancy there usually is a low blood pressure and a fast pulse, but he has observed in a few cases a drop in blood pressure associated with a slow pulse rate—in 1 case 46 per minute.

In 213 major gynecological operations, 23 or 10.8 per cent had a low blood pressure. Of these, 8 or 34.7 per cent had a pulse rate below 100 per minute, while the same number had a pulse rate not to exceed 120 per minute. In the following case the steady fall in blood pressure is associated with a slow pulse rate.

No. 30874. A housekeeper aged 54 years, came to the University of Chicago Clinics on November 7, 1931, because of continued vaginal discharge and bleeding for 18 months and pain in the legs and back for 1 month.

Physical examination revealed a well developed woman weighing 49 kilograms. The heart was of normal size. The heart rate was slightly accelerated, but regular. The blood pressure was 148/104. The lungs were normal. Blood examination revealed red blood cells, 4,310,000; hemoglobin, 75 per cent; white blood cells, 13,350. The urine was normal. The

pre-operative diagnosis was suspected carcinoma of the corpus uteri.

On the day following admission because of a mild febrile reaction only a dilatation and curettage and examination were performed under a 20 minute ethylene-oxygen anesthesia.

Four days later (November 12, 1930) the febrile course had subsided so a total hysterectomy was performed. After a pre-operative 0.010 gram of morphine and 0.0003 gram of hyoscine ethylene-oxygen with the addition of $\frac{1}{4}$ ounce of ether was administered for 1 hour and 55 minutes. The blood loss was minimal. Following the removal of the uterus there was a noticeable drop in blood pressure, which 35 minutes later was 60/40 (Fig. 4). The pulse rate was 88 regular and of fair quality. The skin was warm and dry. Caffeine sodium benzoate (2 cubic centimeters) was given hypodermically however there was but a slight increase in the blood pressure. At the termination of the operation 35 minutes later the blood pressure was 70/58, the pulse rate 96 per minute and of only fair quality. The patient's body was still warm, but she responded slowly. One cubic centimeter of digifolin was given hypodermically.

Immediately upon returning to her room the patient was given 1 cubic centimeter digifolin, and 1 cubic centimeter ephedrine hypodermically and 1500 cubic centimeters Ringer's solution by hypodermoclysis. Patient was conscious. Thirty minutes later the blood pressure was 90/70 and the pulse was hardly perceptible. As the pulse remained weak 1 hour later 500 cubic centimeters of 10 per cent glucose were administered intravenously and the pulse became stronger. The pulse rate was 94 per minute and the blood pressure 100/70. Eight hours

Fig. 6

later the blood pressure was 124/100 however the skin was cold and clammy and the pulse almost imperceptible. Codeine and alcohol were administered, but the patient did not sleep for 24 hours following operation. The day after operation 1500 cubic centimeters of subcutaneous Ringer's solution were administered as the patient seemed dehydrated. The pulse was now of good quality and the patient made an uneventful recovery.

In 115 bladder and prostate operations 8 or 6.9 per cent had a blood pressure below 80 systolic. All of these 8 patients had an associated slow pulse rate, it being below 100 per minute in 6 instances. This group consisted of individuals from 50 to 70 years of age. All presented a moderate to an advanced degree of arteriosclerosis.

Only 3 of 26 kidney operations were associated with a marked fall in blood pressure. Two of these 3 also had a slow pulse.

Table III presents cases not previously discussed and illustrates the frequency with which a low blood pressure was associated with a slow pulse rate.

Wiggers (1923) states that the arterial blood pressure fall in hemorrhage is associated with a rapid pulse. Although we found hemorrhage to be frequently associated with a blood pressure fall and pulse rise, we have noted several instances where the blood pressure fall is not associated with a pulse rise. Figure 5 illustrates the reaction to hemorrhage in a woman 54 years of age undergoing open reduction and fixation with bone transplantation for ununited fracture of the neck of the femur under ethylene-oxygen anesthesia, preceded by morphine sulphate gram 0.010 and atropine sulphate gram 0.0004. The patient required 1500 cubic centimeters normal salt solution intravenously in the operating room following operation to bring her blood pressure and general condition back to a satisfactory level. Preceding operation this patient had a blood pressure of 188/120. For the first week following operation the highest blood pressure reading was 120/78. The postoperative pulse was normal.

Fig. 7

Does general anesthesia remove the changes in blood pressure and pulse rate produced by the fear of the operation or the anesthesia? Toxic thyroids usually develop a more stable blood pressure and pulse after the induction of general (ethylene-oxygen) anesthesia. Fear may cause either a rise or a fall in blood pressure with usually an associated rise in pulse rate.

The blood pressure fall that occasionally occurs under local anesthesia may be attributed to a toxic reaction from the anesthetic agent employed. According to Eggleston and Hatcher (1919) intravenous administration in cats of toxic doses of cocaine and procaine produces an abrupt fall of blood pressure with a slow heart usually, due to weakening of the heart muscle. They also report one case of intoxication in a woman following novocain injection, with the development of clonic convulsions and slowing of the pulse 8 minutes later. We have never observed convulsive phenomena.

TABLE III

Operations	No.	BP below 80 (Per cent of total)		BP 80 or less pulse 100 or less		BP 80 or less pulse 120 or less		BP above 80 pulse above 120

Thyroid	42	5	11.9	0	0	None	None	4	9.5

The possibility of a fainting or psychic reaction has to be excluded. We have observed a

Fig. 6.

slowing in pulse rate associated with a rapid fall in blood pressure both in patients under local anesthesia and in very apprehensive or fainting individuals where no anesthetic agent is employed.

The manifestations mentioned of a slowing in pulse rate associated with a marked drop in blood pressure occurred in patients in both the upright and recumbent positions. Figure 6 illustrates the slowing and weakening of the pulse until it was imperceptible associated with a marked fall in blood pressure 5 minutes after novocain infiltration for an attempted encephalogram. Nausea, pallor, and cold clammy perspiration were associated with the pulse and blood pressure changes. A comparable picture was seen in a brief study made of tonsillectomies under cocaine anesthesia. The sitting position was employed in these two types of surgery. The same reactions have been observed in patients in the recumbent position under novocain anesthesia (Fig. 7).

In order to eliminate the possibility of a toxic reaction from the anesthetic agent employed, studies of the blood pressure and pulse changes during the drawing of blood for Wassermann and Kahn tests were made. Of 44 cases studied, 5 had a marked drop in blood pressure and a slowing of the pulse rate, and one patient lost consciousness. The rapid blood pressure fall that occurs with syncope has been reported (Tocantins 1930). Figure 8

illustrates not only the loss of blood pressure sounds with a loss of consciousness in fainting but also the slowing to loss of pulse beat. Upon the return to consciousness there was a rapid return of blood pressure and a slow increase in pulse rate. Forty minutes later neither pulse nor blood pressure had reached a normal level.

A blood pressure fall was observed in a patient 18 years of age during the excision of a sinus of the buttocks. No anesthetic agent was employed because of the presence of sacral anesthesia resulting from a spina bifida.

It is of interest to note the changes in pulse and blood pressure associated with the use of a constrictor. The application of the constrictor usually does not produce much change in blood pressure. There may be some rise especially if the patient is not entirely anesthetized. Operation on the bloodless area, as for osteomyelitis in adults, usually does not cause a blood pressure fall. In children, a very gradual fall may occur. After removal of the constrictor in a small number there is no change in blood pressure and pulse. Of 75 cases 65 had a fall in blood pressure. Of these 31 had a fall in pulse rate, 27 had no change in pulse rate, while 10 had a pulse rise.

DEDUCTIONS

Frequent instances have been presented where the drop in blood pressure has been our earliest warning of a change in the patient's

general condition. This suggests the importance of the more frequent employment of blood pressure observations during critical procedures to enable us to institute earlier restorative measures. The time factor is of great importance as regards improvement in the patient's general condition when the need arises for stimulants, intravenous fluids and blood transfusion. The rapid improvement following the timely administration of a blood transfusion is noteworthy. It is apparent that changes in the quality of the pulse must be carefully observed as well as changes in the pulse rate.

SUMMARY

A marked blood pressure fall may occur without an increase in pulse rate.

A patient's condition may reach an alarming level some time before an increase in pulse rate occurs.

Blood pressure changes rather than an increase in pulse rate frequently present the earliest evidence of circulatory failure.

This work was done under the direction of Professors D. F. Houston and Edmund Andrews, whom the writer wishes to thank for their many helpful suggestions.

Fig. 2 Gastric erosion

Sections of resected stomachs taken beyond the ulcer proper show in most cases evidence of gastritis with hyperacidity, gastric erosion and a marked increase in number and size of follicles (Fig. 2). Therefore because of this abnormal change in the gastric mucosa, resection is considered the best form of treatment.

In many cases of early gastric cancer diagnosis as such cannot be made until after operation. Pommersheim of this clinic found 47 cases of carcinoma superimposed on old calloused ulcers in a total of 530 patients examined or about 9 per cent.

Triplicate	5

Fig. 3. Papillary degeneration old calloused ulcer. Precancerous lesion.

Clairmont states that about 10 per cent of calloused gastric ulcers become malignant but that 50 per cent of those which are prepyloric have a predisposition to malignancy. A. J. Walton believes that 10 per cent of gastric ulcers become malignant, Maresch considers the incidence to be between 10 to 15 per cent. Accepting as a fact that a certain percentage of gastric ulcers become malignant, resection offers the best chance of cure (Figs. 3 to 8).

Figure 3 shows a gross section of an old calloused ulcer at the precancerous stage. There is a decided papillary overgrowth and Figure 4 (microscopic section) shows the earliest change which we can regard as beginning cancer. A further advanced lesion is seen in Figure 5 also with history of a long standing ulcer on the lesser

Fig. 4. Microscopic appearance of preceding ulcer

Fig 5 Carcinoma of lesser curvature

curvature. Figure 6 shows the gross, and Figure 7 the microscopic appearance of the ulcer with definite carcinomatous change. Both of these cases were diagnosed by X ray examination as

Fig 7 Carcinomatous ulcer Microscopic appearance of preceding ulcer

Fig 6 Carcinomatous ulcer X ray diagnosis of ulcer of lesser curvature 6 years before operation, medical treatment in interval

ulcer of the lesser curvature 5 and 6 years previous to operation. A further similarity between the papillary degeneration of an old ulcer and cancer is demonstrated in Figures 8 and 9.

The detailed technique of Professor Verébely's method of stomach resection was first reported in 1927 by Neuber. He reported results on 226 cases operated upon up to that time. To review briefly without a detailed report as to pre-operative care, anesthesia, and step by step procedure, I will mention only the general principles which are embodied in this method:

- 1 Application of the sewing clamp to the stomach after ligation of the vessels (Figs. 10A and 10B)

- 2 Incision between two rows of metal sutures preventing escape of any gastric content (Fig. 11)

- 3 Removal of stomach and portion of duodenum (containing ulcer when possible)¹

- 4 Closure of duodenum—continuous catgut for the muscularis and mucosa, and interrupted sutures for the serosa.

- 5 Anastomosis between stomach and jejunum, the lower corner of stomach is resected, suture line fixed below and through mesocolon (Fig. 12)

The operation is performed under local anesthesia—usually splanchnic anesthesia is employed though spinal and infiltration methods have also been used.

After this method of resection, all patients are sent to the X ray laboratory for fluoroscopic examination on the eighth or tenth postoperative day. Dr. Ratkoczy, director, has found that there is no precipitate emptying of the stomach.

¹ When it is not possible to excise duodenum below ulcer the method of Finsterlin is followed, resection by inclusion of the ulcer.

Fig. 8. Papillary degeneration of gastric mucosa

Fig. 9. Papillary carcinoma

The metal sutures have in no case caused any difficulty, they usually slough out and are passed by bowel in 2 or 3 weeks.

The mortality for all cases following gastric resection was 7.8 per cent following gastro-enterostomy, 3.5 per cent. Since 1923, the corner anastomosis of Professor Verebely has been exclusively followed and the mortality has been lowered to 4.8 per cent. This is inclusive for all resections, for carcinoma perforated ulcers, etc. In operation for peptic ulcer alone the mortality was 4.5 per cent following gastro-enterostomy, 1.8 per cent after exclusion of pylorus and gastro-enterostomy, and now 0.5 per cent after resection with the use of the sewing clamp and corner anastomosis.

Any method of treatment can be fairly judged not alone on the mortality statistics but by the

end results obtained especially if the method has been used in a large number of cases over a long period of time and the follow up shows continued good results. Since 1923 a careful postoperative check up has been made on all patients on whom resections were performed. Previous to that time postoperative records on ulcer and cancer patients operated upon had been kept but the data were not as complete. The sum total of all resections performed has shown good results in 81.4 per cent of the cases, or 1,954 fair results 16.6 per cent, or 398 cases bad results 2 per cent, or 48 cases.

After palliative operations—exclusion with gastro-enterostomy etc.—we found good results in 49 per cent, fair results in 33 per cent and bad results in 18 per cent.

After resection with corner anastomosis accord-

Fig. 10. A, Sewing clamp to be applied to stomach. B Application of sewing clamp to stomach (from movie film)

Fig. 17. Stomach locked between two rows of metal sutures.

ing to Professor Verebely, good results were obtained in 90 per cent, fair results in 8.5 per cent, poor results in 1.5 per cent.

CONCLUSION

A method of treatment is reviewed and the results after a 9 year period have been summarized and have been found to be more satisfactory both in regard to mortality and permanency than are the results from any of the other methods of treatment.

ACCESSORY thyroid glands or aberrant nodules of thyroid tissue are found comparatively frequently in the neck base of the tongue and structures of the thorax. Also cell masses identifiable as thyroid tissue are not infrequently noted in ovarian dermoid cysts or teratomata (19 per cent according to Koucky). But isolated nodules of thyroid tissue in the ovary unassociated with other heterotopic tissues are so rarely seen that their occurrence deserves to be recorded.

The significance of thyroid tissue in the ovary in which thyroid structures make up practically all of the tumor has been widely considered. Gottschalk, in 1899 described a tumor of the ovary which he believed had arisen from malignant change in a graafian follicle. His description corresponded to that of a tumor of thyroid tissue but he called it folliculoma malignum ovarii. Kretschmar in 1901 reported a similar tumor in which he believed he could demonstrate the primary tumor elements arising from the lining cells of a lymph space. He therefore designated the tumor an endothelioma. Katsurada also in 1901 described briefly a teratoma containing thyroid tissue. The following year Pick presented before the Berliner medizinische Gesellschaft a series of 21 dermoid tumors of the ovary 7 of which contained thyroid tissue. His evidence was convincing that the thyroid tissue in these tumors was part of a teratomatous growth in which the endodermal elements of thyroid anlage had undergone excessive development with partial or complete suppression of other tissue elements. He placed the cases of Gottschalk and Kretschmar in the same category. This gave rise to a series of heated arguments before this society. Kretschmar later admitted that his tumor consisted of thyroid tissue but he believed that it had metastasized in spite of the fact that a few small areas of bony tissue were found. He explained these on the basis of metaplasia of the connective tissue. Following Pick's intensive study of this type of tumor and of teratomata in general, numerous studies were reported from various countries. Most observers supported the teratomatous origin of these tumors. Walther made serial sections of three ovarian tumors which

grossly seemed to consist only of thyroid tissue. In one of these he found a small cartilaginous mass, and in another a small area of squamous epithelium and sebaceous and sweat glands. The third and largest tumor consisted of thyroid tissue except for a little ovarian stroma in the capsule. This work gave material support to Pick's hypothesis. Saxer about the same time contributed additional evidence by describing his frequently quoted case the ovary of which was entirely normal except for the inclusion of a single tooth thus a dental anlage had developed with suppression of all other types of tissue.

Bauer and Borst, among others have refuted the teratomatous origin of these tumors. Bauer demonstrated a transition from a typical papillary cystadenoma into thyroid like tissue and stated his belief that most so called tumors of thyroid tissue of the ovary are atypical cystadenomata. Borst presented the view that a follicular adenoma might give rise to thyroid characteristics and have nothing to do with a teratoma. In this regard the view of Ribbert may be recalled that cystadenomata of the ovary are teratomatous in origin having an endodermal anlage and are therefore frequently associated with dermoid cysts. Bell did not accept this view since he believes that the thyroid like tumors arise from a peculiar colloid degeneration of cystadenomata. Strong is inclined to agree with this view except in rare instances. However most observers agree with Pick that these tumors are of teratomatous origin.

To the clinician the most interesting feature of this type of tumor is its capacity for secreting thyroxin. Certainly in most of the cases reported the presence of hyperthyroidism was not mentioned. Frankl explained this lack of physiological function on the basis of a relatively meager intercapillary blood supply. The presumable thyroid secretion is thus not adequately absorbed into the blood stream. A few cases have been reported, however, in which some physiological effect was believed to have been demonstrated. Kovács reported the case of a woman aged 33 years who had an enlarged thyroid gland and mild symptoms of hyperthyroidism. A tumor of thyroid tissue was removed from the ovary. Nine months

Fig. Ovarian tumor removed at operation. Some of the large peripheral cysts have collapsed but the colloid of the central portions is preserved. The mass measured 14 by 8 by 7 centimeters, and weighed 210 grams. Case 1.

after operation the symptoms of hyperthyroidism had improved. Trapl reported a case in which hyperthyroidism developed after removal of a thyroid tumor from the ovary. He explained this phenomenon as compensatory hyperfunction of the thyroid gland. In a case reported by Moench, a cardiac irregularity which had been considered functional, cleared up after removal of a cyst from the right ovary which was found to contain thyroid tissue. Morgan presented a necropsy report in which a markedly atrophic thyroid gland was associated with a tumor of the left ovary. He believed that the teratomatous thyroid tissue was compensating for the atrophic thyroid gland. Outerbridge after reviewing all the reported cases, came to the conclusion that the aberrant thyroid tissue has little if any functional significance. It is with this question of functional activity in mind that the following cases are presented.

REPORT OF CASES

CASE 1—A woman, aged 40 years, first came to the clinic September 13, 1929. At this time she gave a history of mild hyperthyroidism. Her highest basal metabolic rate was +15, and the pulse rate was consistently around 100 beats each minute. A pelvic tumor was also noted. She was advised to have thyroidectomy first, and later to have the tumor in the pelvis removed.

September 30, subtotal thyroidectomy was performed with double resection and removal of the larynx. The pathologist reported hemorrhagic cystic degenerating colloid and fetal adenoma in a colloid thyroid gland. The tissue removed weighed 36 grams. Recovery was uneventful. October 16, left oophorectomy was performed for multilocular cystic tumor of the left ovary. The pathologist reported that the tumor (Figs. 1 and 2) consisted of hemorrhagic, fibrous, hyaline, cystic, degenerating colloid and fetal thyroid adenoma. At the time of the operation a great deal of milky ascitic fluid escaped from the abdomen.

The patient was discharged in fair condition 19 days after the operation. The final basal metabolic rate after the two operations was -4.

The patient returned December 11, with marked anasarca which had gradually developed since she left the clinic in October. The only abnormality noted on examinations of the blood and urine was albumin, grade 1 in the urine. Paracentesis was done with removal of 1,700 cubic centimeters of straw colored fluid. The edema was treated with salyrgan with good response.

Between December 11, 1929, and October 2, 1931 the patient returned to the clinic a number of times for paracentesis and study always with the same results, except that a renal stone and hematuria was discovered on one occasion. Roentgen rays were applied over the pelvis and abdomen without relief of anasarca. The patient's general condition remained good in spite of the fact that she had had paracentesis with removal of about 9,500 cubic centimeters of fluid every 10 days.

October 6, 1931 abdominal exploration was carried out. A large amount of ascitic fluid was evacuated, but no other abnormalities were noted. All peritoneal surfaces appeared normal. October 30, after discharge from hospital, the patient began to complain of severe abdominal cramping, requiring morphine. Anasarca and cardiac embarrassment were noted. Her condition gradually became worse and the leucocyte count was high. Death occurred November 1.

Necropsy disclosed a remarkable state, apparently in no way related to the previous hyperthyroidism and ovarian tumor. In addition to 10,000 cubic centimeters of ascitic fluid, there was complete thrombosis of the portal system. The thrombus was recent in the mesenteric veins, but old and well organized and partially canalized in the splenic vein. The left branch of the portal vein at the hilum of the liver was reduced to a fibrous band. The anasarca was apparently dependent on the thrombotic process which had suddenly increased, and ended fatally. No recurrence of tumor was noted in the pelvis, all peritoneal surfaces being smooth. Figure 3 shows the structure of the thyroid gland removed at necropsy.

On further study of the cystic ovarian tumor which was removed ovarian stroma was found only in its peripheral portions; this was infiltrated with lymphocytes. Most of the blocks, cut from various parts of the tumor contained areas structurally typical of adult thyroid tissue whereas (Fig. 3) in other areas were the small, closely packed acini seen in so called fetal adenoma. Here and there were areas of ordematous and degenerating hyaline stroma containing scattered small groups of thyroid-like acini. Teratomatous structures other than thyroid tissue were not found, except one small cystic space which was lined by an atypical stratified epithelium six to eight cells deep which may possibly have represented ectodermal elements.

The important question, which unfortunately can never be answered definitely is whether the patient's hyperthyroidism may not have been partially or completely due to the large mass of thyroid tissue in the left ovary. The weight of the mass, on removal, was 210 grams whereas the tissue removed from the thyroid gland weighed

Fig. 2. Ovarian mass in which may be seen evidence of hyperplasia of the thyroid epithelium in some of the larger acini. Case 2.

Fig. 3. Specimen of thyroid gland removed at necropsy (Fig. 2). Slight evidence of hyperplasia may be noted. Case 2.

only 36 grams. In the ovarian tumor occasional areas of hyperplasia were noted (Fig. 2). These were also present in the thyroid gland. It is unfortunate that basal metabolic rates were not taken in the interval between the two operations. The pulse curve after the two operations however affords some information. Seven days after the thyroidectomy (first operation) the pulse came down to 90 beats each minute. This was the lowest pulse rate recorded during that period in hospital. The patient was dismissed from the hospital on the eighth day with a pulse rate of 100. Following the removal of the thyroid tumor of the ovary the pulse rate was 70 on the fifth and sixth postoperative days and although it did not remain at this level it maintained a lower level than previously. The basal metabolic rate after both operations was -4 but this is of no assistance in answering the question. The subsequent events with the rapid reaccumulation of ascites over a period of 2 years, were probably in no way related to the hyperthyroidism but were no doubt due to portal thrombosis. The basal metabolic rate reported 10 days before death was -4 .

CASE 2. A woman aged 55 years, presented herself at the clinic November 4, 1927, with a history of swelling of the abdomen for 4 months which began following an attack of severe pain in the region of the urinary bladder. The abdomen had been tapped three times before admission with removal of about 9,500 to 11,000 cubic centimeters of fluid each time. She had lost more than 15 pounds in weight during her illness and felt weak, and her appetite was poor. She had passed through a normal menopause at the age of 45 years. There had been no pelvic symptoms until the onset of the present illness when suprapubic pain developed.

On examination, evidence of loss of weight was most apparent about the face, neck, and arms. The thyroid gland

was normal to palpation. The heart was normal except for a rapid rate which varied between 80 and 110 before operation. The abdomen was markedly distended with fluid so that organs could not be felt. Pelvic examination likewise was negative. Roentgenograms of the abdomen and thorax study of chemical changes in the blood as well as tests of hepatic function all proved to be within normal limits. Achlorhydria was the only abnormal laboratory finding. The basal metabolic rate was not taken. Diuretic response to salyrgan and ammonium nitrate was very slow.

Abdominal exploration was performed November 16 with the withdrawal of a large amount of clear fluid. The liver was normal to palpation, as was the peritoneum. There was a tumor of the right ovary which was somewhat adherent with considerable inflammatory reaction in the cul-de-sac, but without evidences of malignancy. The tumor was removed, without disturbing the uterus and left ovary. Pathological examination revealed the right ovary to be replaced by a cystic mass weighing 45 grams. It contained a fibroma and tissue which grossly and microscopically resembled adult and fetal thyroid tissue with areas of undifferentiated fetal thyroid tissue (Fig. 4). Certain areas showed papillary projections covered with cuboidal or columnar epithelium and typical hyperplasia. In only one area was there any tissue suggestive of ovarian stroma and this was without follicles.

The patient recovered rather slowly but steadily and there was no tendency to reaccumulation of fluid. The tendency toward tachycardia continued, although the pulse rate seldom was more than 100 after operation. Compound solution of iodine 30 minims was given for 4 days after operation, and again before the patient left the hospital. Two basal metabolic rates, taken on the thirteenth and twentieth days after operation were $+32$ and $+50$ respectively. However neither of these determinations was considered satisfactory by the technicians. The patient manifested few symptoms of hyperthyroidism, although she was nervous and "jumpy" and the pulse rate was usually above normal. The weight, after operation, with the loss of fluid, was 58 pounds less than the normal weight of 103 pounds. The patient was dismissed feeling well 23 days after operation. She was heard from numerous times until June, 1930, which was 2½ years after operation and each of these times she reported that her condition was excellent.

Fig. 4. Frozen section from ovarian tumor. Although this is a thick section, the epithelium may be seen in folds typical of hyperplasia, in the larger acini. Case 3.

Although we have no absolute evidence of hyperthyroidism in this case, we made several suggestive observations most important of which are tachycardia, marked nervousness, and loss of weight. It is unfortunate that the basal metabolic rate was not taken before operation. Although the two rates taken after operation were not entirely satisfactory, it is probable that the rate was somewhat elevated at that time. The rapid accumulation of ascitic fluid was an interesting feature in this case. Although ascites occurs commonly with malignant ovarian tumors, its occurrence with benign tumors of the ovary is not common. It is said to occur in 7 to 8 per cent of ovarian cystomata, however, and it is possible that the peritoneal irritation produced by the tumors causes the outpouring of fluid. This is a possible explanation in this case, since there was considerable inflammatory reaction in the pelvis about the tumor.

CASE 3. A woman, aged 63 years, came to the clinic October 24, 1916, because of constipation. She had always been nervous, and had had a rapid heart beat with slight tremor which had not been progressive.

Examination revealed a pulse rate of 14 beats each minute; the blood pressure in millimeters of mercury was 160 systolic and 60 diastolic. The heart was enlarged slightly to the left. A coarse tremor of the hands was present, which could be partially controlled voluntarily. In the pelvis a firm nodular mass was felt to the right and posterior to the fundus of the uterus.

Subtotal abdominal hysterectomy was performed with removal of both ovaries and fallopian tubes. The pathologist found that the right ovary had been replaced by a mass of vascular tissue 7 by 6 by 5 centimeters. The cut surface was honeycombed with multiple tiny cysts filled with a colloid substance, and some very firm central masses. On microscopic examination, the mass resembled thyroid tissue both of the fetal and adult types with slight evidences of

hyperplasia. The firm central masses were made up of degenerated material containing coarsely granular calcium masses. Ovarian tissue was not identified.

It is unfortunate that metabolic studies were not made in this case, but with some evidences of hyperplasia of the thyroid tissue in the tumor it is possible that mild hyperthyroidism was present, as evidenced by the tachycardia. The nervousness may have been significant, the tremor of the hands which was partially voluntarily controlled, may also have been partly on a hyperthyroid basis. We have no data on the subsequent course of the case.

CASE 4. A woman, aged 30 years, first came to the clinic December 20, 1920, at which time a diagnosis was made of tuberculous of the third and fourth lumbar vertebrae, adenomatous thyroid gland, without evidences of hyperthyroidism, and a left ovarian tumor which apparently was not causing symptoms after treatment of the spinal column. She was advised to return in 3 months but she did not return until November 8, 1925, when she gave a history of metrorrhagia for 5 months. The adenoma of the thyroid gland was still present, but without apparent symptoms of hyperthyroidism. The tuberculous lesion of the lumbar vertebrae was well healed. The cervix uteri was markedly eroded and cystic, the fundus was somewhat enlarged, and the mass in the left ovary was estimated to be of about the same size as on the previous examination. Dilatation and curettage of the uterus revealed hypertrophic endometritis. The cervix was cauterized. On examination of the pelvis under anesthesia, further operation was not deemed advisable.

September 28, 1931, the patient returned to the clinic with a history of bloating of the abdomen which had been constant for the last 3 to 5 months. She had gradually gained weight, from 185 to 202 pounds, and noticed a dragging sensation in the pelvis. Examination revealed well marked ascites in addition to obesity and a tumor in left side of the pelvis. A multilocular cyst of the left ovary was removed and a large quantity of ascitic fluid was drained from the peritoneal cavity. The left ovary was found to be replaced by a large multilocular cyst which measured 12 by 9 by 8 centimeters. The largest cyst contained hemorrhagic material adherent to its wall. The other cysts were smaller, and minute honeycombed cysts made up a large part of the mass. Sections taken from numerous areas of the mass showed groups of variously sized alveoli lined with flat or cuboidal epithelial cells, typical of thyroid tissue (Fig. 5). Masses of small cysts made up the walls of the larger cysts. All were filled with rather deeply staining colloid. Many areas gave the appearance of fetal thyroid tissue whereas others appeared definitely hyperplastic. A fairly large irregular mass of polygonal cells with deeply stained nuclei surrounded and penetrated by blood filled spaces, was present in one section (Fig. 6). Here and there was a suggestion of alveolar arrangement. These cells were suggestive of parathyroid structure, but this possibility cannot be proved.

Although this patient had an adenomatous goiter and a large amount of thyroid tissue in the ovary many areas of which showed evidences of hyperplasia, clinical evidence of hyperthyroidism was not displayed. For this reason metabolic rates were not determined. One may speculate

Fig. 5. Typical thyroid structure in ovarian tumor. Hyperplasia is clearly shown in the papillary projections of columnar epithelium into the acinar spaces. Case 4.

Fig. 6. Mass of polygonal cells resembling parathyroid tissue. The grayish spaces are filled with erythrocytes. Case 4.

concerning the occurrence of cells similar to parathyroid cells but there is no means of proving the identity of this mass of tissue. We have found reference to a similar type of tumor in the literature. Moench found masses of cells which closely resembled parathyroid cells in a tumor of thyroid tissue of the ovary. This case is included because of the nature of the tumor and the ascites without clinical hyperthyroidism in spite of definite hyperplasia of the thyroid epithelium in some areas.

CASE 5. A woman aged 35 years, first came to the clinic February 9, 1931. She had begun to have "heart trouble" in the autumn of 1930. In December she noted a swelling of the neck which increased rapidly. Later her voice changed and she had difficulty in talking. Dyspnea and occasionally stridor, dysphagia, weakness, nervousness, and loss of weight were among her complaints.

The patient appeared to be mentally dazed, stimulated and very weak. The pulse rate was 135 beats each minute; the blood pressure in millimeters of mercury was 140 systolic and 70 diastolic. The basal metabolic rate was +82. The thyroid gland was enlarged bilaterally with bruit over all poles. Pelvic examination revealed a 3 to 4 months pregnancy. She was hospitalized but remained restless and irrational in spite of all treatment until February 15 when she became quiet and mentally more clear. Basal metabolic rate March 5 was +47. She was allowed to return home with instructions to take compound solution of iodine.

The patient returned April 14 with a basal metabolic rate of +78 per cent. Two injections of hot water were given into the thyroid gland, and April 22 the superior thyroid vessels on both sides were divided and ligated. Recovery was uneventful.

The patient returned October 10. She had had a premature delivery at home May 16 without complications. Her general condition had improved somewhat although weight continued to decrease. The thyroid gland was still large. The basal metabolic rate was +65 per cent, the blood pressure was 160 systolic and 88 diastolic. The pulse rate was 130. October 27 the right lobe of the thyroid gland was

resected. The pathologist reported a few small hemorrhagic, fibrous, cystic, degenerating colloid and fetal adenomata in a hypertrophic, parenchymatous gland. October 27 the patient's heart was fibrillating rapidly and she was irrational and coughing continuously. Pneumonia developed in the base of the left lung October 30 and death occurred 2 days later.

At postmortem examination, in addition to a large left lobe of the thyroid gland which still remained (weight 150 grams) and rather marked atrophy of the liver both grossly and microscopically, a rounded nodule was found buried in the right ovary. This measured 6 millimeters in diameter was dark red on its cut surface with a fibrous capsule surrounding it (Fig. 7). The ovary appeared otherwise normal except for numerous cortical cysts. The left ovary also contained numerous small cysts, but no similar nodules. Microscopic study of the nodule from the right ovary revealed a tumor made up of typical adult thyroid tissue containing a thin colloid substance. At one edge of the nodule definite evidences of hyperplasia were noted (Fig. 8). A fibrous capsule surrounded the nodule on all sides, cutting it off completely from the surrounding ovarian stroma. One small group of cells at the periphery adjacent to the capsule showed an atypical structure and remained unidentified, although the cells were suggestive of embryonic ependymal cells. The remainder of the thyroid gland (left lobe) was typical of the tissue under iodine treatment. The colloid was pale and few evidences of hyperplasia remained.

This case of frank hyperthyroidism is presented because of the small nodule of thyroid tissue in the right ovary. In this case there is no doubt that the hyperthyroidism was due to hyperplasia of the thyroid gland itself. The interesting feature is the fact that the small nodule of thyroid tissue in the ovary also presented evidences of hyperplasia. The ovarian nodule showed more evidences of hyperplasia than the original portions removed from the thyroid gland. An additional interesting point is the small size (6 millimeters) of the nodule.

CASE 6. A woman, aged 43 years, presented herself at the clinic July 15, 1924, because of nervousness and short

Fig. 7. Right ovary and tube. The ovary has been split longitudinally and laid open. The left on the cut surface may be seen a dark rounded mass, which grossly and microscopically resembles thyroid tissue. Case 5.

Fig. 8. Thyroid nodule (Fig. 7). Epithelial hyperplasia in some of the larger acini, and ovarian stroma with follicular cysts at the upper border of the section may be seen. Case 5.

ness of breath which had been present for several years. She also complained of tachycardia and palpitation, and had noticed slight tremor of the hands. There had been no increased sweating, she felt chilly rather than warm.

On examination the patient appeared to be stimulated. The pulse rate was 90 beats each minute. Multiple adenomas of the thyroid gland, enlarged myomatous uterus and a tumor about 7 centimeters in diameter in the position of the right ovary were found. It was decided that hyperthyroidism was not present and the metabolic rate was not determined. Exploration of the pelvis was advised. To be followed in several weeks by thyroidectomy.

At operation a degenerating myoma of the uterus and a cystic tumor of the right ovary were found, and removed. Pathological examination showed the right ovary to be replaced by a cystic mass measuring 8 by 7 centimeters and having a thick wall and a fatty semisolid content without hair. Several small nodules were scattered over the inner surface of the cyst. These on cut surface were honey-combed with tiny cystic spaces filled with colloid material. Microscopic sections disclosed a thick, fibrous-walled cyst lined by columnar epithelium in some areas, and broken up into irregular masses which were covered with columnar and cuboidal epithelium. The nodules mentioned were made up of thyroid-like acini filled with colloid. Marked hyperplasia of the acinar epithelium was seen in irregular areas. The cells were cuboidal or columnar with large, centrally placed nuclei and the acini in these areas were closely crowded together and small. Infiltration of the interstitial tissues was not seen and few mitotic figures were present.

Symptoms of nervousness, palpitation and tachycardia suggested hyperthyroidism in this case but this was not substantiated by the entire clinical picture. The patient did not remain for the thyroidectomy and was never heard from subsequently, so we do not know if the symptoms improved. The interesting feature of this case is the presence of very marked hyperplasia of the thyroid tissue in the ovary. The greater part of

the tumor was made up of typical ovarian cyst adenoma with nodules of the hyperplastic thyroid tissue scattered throughout. It seems possible that slight hyperthyroidism existed. Photomicrographs of this tumor are not presented because of the poor fixation of the tissues.

GENERAL COMMENT

Although many of the cases reported in the literature are definitely not cases of hyperthyroidism there is present nevertheless a potentiality for excess secretion of thyroid tissue. But just as large adenomatous goiters may not produce symptoms of hyperthyroidism, so a mass of thyroid tissue in the ovary may be present without causing hyperthyroidism. The iodine content of these tumors has been determined quantitatively by Meyer King and Norris and others and it has been suggested that an appreciable amount of iodine speaks for functional activity of the tissue. Outerbridge determined the presence of iodine qualitatively by Jones differential staining method. Although iodine has been found in other organs such as muscles, suprarenal glands, thymus and spleen it is said by Crofts to be present in the thyroid gland in larger quantities than in any other organ except the parathyroid glands. The iodine content of the thyroid gland varies with the age of the patient, and also with the iodine content of the diet. Ordmann estimated the iodine content of the thyroid gland at approximately 0.1 per cent.

The iodine content of three of the tumors in this series was determined. The large tumor in Case 1 contained 0.105 per cent of iodine, dry weight.

The tumor in Case 4 contained 0.011 per cent of iodine dry weight and that in Case 3 contained 0.031 per cent dry weight. The tissues had been fixed in formalin solution and it is probable that a considerable proportion of the iodine had been dissolved by the solution. An appreciable amount of iodine was found in the three tumors examined greatest in the case of the large tumor in Case 1. This patient had had mild hyperthyroidism and it is possible that the iodine she received accounts for the greater concentration of iodine in the tumor. In Cases 3 and 4 iodine had not been given. The thyroid tissue in the tumor in Case 3 contained the least amount of iodine and also the least hyperplasia of the epithelium.

The question of malignant change in these tumors has been of interest to the clinician and surgeon. Certain observers believe that tumors consisting entirely of thyroid tissue are all potentially malignant because they have overgrown all other tissue elements. From the cases reported in the literature as well as from our own cases there seems to be little evidence of malignancy. It is Ewing's belief that some solid carcinomata of the ovary may be derivatives of teratoid thyroid tissue. Certainly the majority of cases are neither clinically nor pathologically malignant. In Case 2 removal of the tumor afforded complete relief of all symptoms and ascites did not return. In Case 1, which later came to necropsy, there was no evidence of metastasis from the tumor death having been due to diffuse venous thrombosis of the portal system and elsewhere. Similarly in many cases from the literature the patients recovered completely after removal of the tumor. However, a few definitely malignant cases have been reported by Katsurada, Norris, Proescher and Roddy, Polano and others. Ulesko-Stroganowa reported the only bilateral tumor of thyroid tissue of the ovaries on record. Although histological evidences of malignancy were not present, she believed that the bilaterality of the tumor was evidence of metastasis from one ovary to the other.

The not infrequent occurrence of ascites with these tumors has been of clinical interest although apparently of no prognostic significance. In Cases 2 and 4 the ascites showed no tendency to recur after operation whereas in Case 1 although the rapidly accumulating fluid was at first thought to be evidence of malignancy it could not be found at operation. This was later confirmed at necropsy. In Case 6 in which there was marked evidences of hyperplasia, ascites was not present. Frank has observed ascites in about 50 per cent of these tumors and cases without ascites have been

reported since he made this observation his figure therefore seems far too high. Warren stated that 7.9 per cent of ovarian cystomata are associated with ascites and it would seem that similar causes probably operate to produce ascites with ovarian tumors of various types and that therefore this figure (7.9 per cent) is a better estimate than 50 per cent. The presence of ascites is obviously not necessarily indicative of malignancy.

SUMMARY AND CONCLUSIONS

Cases of ovarian tumor containing large amounts of thyroid tissue are presented. In one case the ovarian tumor contained nodules of hyperplastic thyroid tissue.

Tumors of thyroid tissue in the ovary are probably of the nature of teratomata.

Since these tumors are of thyroid tissue they are potential sources of thyroxin and in some cases seem to produce hyperthyroidism.

Three of the tumors were analyzed for iodine and an appreciable amount was found.

Hyperplasia of the thyroid epithelium in varying degrees is commonly observed in these tumors.

Malignant changes were not observed in the tumors reported in this series.

Ascites is not infrequently an accompaniment of these tumors.

COMPOUND INTRA-UTERINE AND EXTRA-UTERINE (LITHOPEDION) PREGNANCY

P BROOKS BLAND M.D. F.A.C.S. LEOPOLD GOLDSTEIN M.D., AND WILLIAM W. BOLTON M.D.
PHILADELPHIA

From the Department of Obstetrics, Jefferson Medical College Hospital

CALCIFIED fetuses or lithopedions have been recognized for centuries and have been reported from time to time in the literature. The earliest cases on record according to Dorland are those of Venetiss 1505, Albosius 1597 and Densingeus 1661. In 1881 Kuechenmeister collected 45 cases of various forms of fetal calcification recorded during the 200 year period antedating 1880.

Lithopedions have occasionally been discovered during the performance of operations for various pelvic neoplasms and they are sometimes discovered accidentally at autopsy. In many instances it has been observed, that patients have successfully passed through one or more full term pregnancies, with birth of healthy children without the extrinsic gestation giving rise to difficulty.

In exceptional instances the presence of an extra uterine fetal mass is discovered during the course of a normal intra uterine gestation as in the case recently reported by Balaban and as in the case presented in this paper.

In many of the cases recorded, the ectopic pregnancy has antedated the intra uterine impregnation by many years. As in the case history herewith presented patients are oftentimes entirely unaware of any abnormal abdominal condition, the extra uterine fetus not causing the mildest discomfort.

Since the publication of Kuechenmeister's exhaustive monograph on lithopedions a long list of cases of this rather extraordinary condition has been recorded in the literature.

Masson and Simon in 1928 assembled and published a summarization of the cases recorded from 1582 to 1926. This comprised in the aggregate 174 cases. To this number they added the records of nine lithopedions observed in the Mayo Clinic during a period of 24 years from 1903 to 1926, inclusive. The addition of these cases make a grand total up to 1926 of 183.

In a perusal of the literature since that date we found the records of 13 additional cases (Table I). These were not reported by the writers already mentioned nor had they been referred to subsequently as a collection. These cases with the one herein described make an aggregate of 197

Here it may be of interest to mention that in 1906 one of us (Bland) reported a case of a mummified fetus which was carried by the patient for a period of 15 years. The structure was removed through an abdominal incision. Dissection of the mass after extirpation disclosed that it had probably reached the eighth month of development. During the 15 years the patient has passed successfully through three full term pregnancies.

TYPES OF LITHOPEDIONS

Kuechenmeister developed a hypothesis in an effort to explain the formation of calcified fetuses and classified the different types of this anomaly according to the degree and location of the process as follows:

1. *Lithokelyphos*. In this type calcification and fatty degeneration occur in the exudative lymph surrounding the fetal membranes and in the membranes themselves. As a result a stone like capsule is formed about the fetus, while the fetus itself may undergo slight or massive degenerative changes.

2. *Lithokelyphopedion*. This is a form in which the fetus becomes adherent to the sac, with both the fetus and sac showing widespread infiltration with lime salts. Kuechenmeister believed that this variety resulted when the amniotic fluid escaped or was absorbed, with the membranes themselves becoming tightly wrapped around the fetus.

3. *Lithopedion (stone child or lithocænon)*. This includes in general all types of calcified fetuses, although the term refers especially to the form in which the fetus itself undergoes organization and massive calcification. A true lithopedion forms when the fetus escapes unattached into the peritoneal cavity with or without the enveloping membranes.

Depending on the duration of the gestation outside of the uterus various changes inevitably take place in the fetal structures. Chemical alteration, such as saponification, and a drying process mummification frequently occur. After a time, lime salts are deposited in the fetal tissues or in the membranes, with the result that stone-like masses are finally produced. With these

Fig. Roentgenogram of abdomen showing skeleton of fetus in the left side and lithopedion in the right side.

phenomena present, a fetus is designated a lithopedion.

It has been demonstrated that when mummification of an extra uterine fetus occurs, no trace of the placenta or placental tissue can be found. Mummification results from the absorption of fluids, whereupon the remaining soft parts are converted into hard parchment like material.

COMPOUND INTRA UTERINE AND EXTRA UTERINE PREGNANCY

The synchronous occurrence of an intra uterine pregnancy with an ectopic lithopedion is not often encountered. An advanced extra uterine gestation is usually discovered and surgically removed before lithopedion formation or calcification takes place. Occasionally an advanced gestation out side of the uterus becomes either mummified or calcified. Under such circumstances, the patient may become impregnated once or repeatedly and be delivered normally at term. During this time the old extra uterine pregnancy may escape detection. On the other hand, it may be discovered during the course of an intra uterine pregnancy. The designation of compound pregnancy describes this combination of affairs, namely, an intra uterine gestation associated with a long

TABLE I.—SUMMARY OF THIRTEEN CASES OF LITHOPEDION REPORTED IN THE LITERATURE

Author	Date of report	Features of case
Senger	1915	Patient 57 years old. Rk carcinoma of bladder, lithopedion behind uterus, probably of 14 years duration, having origin in failed abortion.
Kraus	1915	Lithopedion found at autopsy of 70 year old woman, who had had an extra-uterine pregnancy 40 years previously.
3 Evans	1915	Extra uterine pregnancy complicated by lithopedion, removed after operation later 2 years previously.
4 Altmann	1917	Details not obtained.
5 Balaban	1919	Patient 3 years old had lithopedion for 8 years, during which time she had two normal pregnancies. Lithopedion discovered by X-ray examination during course of another pregnancy which terminated normally. Operation was refused.
6 Butler	1919	Patient, age 24, operated upon 3 years previous to present study for ruptured pyogenic pregnancy at 6th time the fetus was not recovered. X-ray examination revealed mummified fetus in upper right quadrant, and it was surgically removed.
7 Doe	1920	Patient, aged 35 years. Full term lithopedion retained for 3 years and successfully removed.
8 Walters	21	Patient, age 34, carried mummified fetus for 7 years, during which period she gave birth to 3 full term children. Lithopedion was successfully removed.
9 Goetz	1921	Patient, age 24, passed through 4 such labor and birth periods. X-ray at admission showed extra uterine fetus with signs of calcification. No symptoms. Lithopedion weighing 10 pounds removed.
10. Engels	1921	Calcified lithopedion of 4 years duration in one tube with recent pregnancy in the other tube. Surgical removal.
Grinn	21	Lithopedion more of 10 years duration, diagnosed by the roentgen-ray removed surgically.
Wissert	1921	Lithopedion of 7 months development carried for 8 years, and removed successfully. One normal pregnancy in the interval.
11. Seale and Emmert	1922	Extra uterine full term fetus diagnosed by X-ray and studied roentgenographically throughout its course of lithopedion formation for 8 years.

standing mummified or calcified fetus in the abdominal cavity.

COMBINED INTRA UTERINE AND EXTRA UTERINE PREGNANCY

At this point it is of interest to mention that not infrequently an intra uterine gestation comes almost synchronously with an extra uterine one. The first case of combined intra uterine and extra-uterine pregnancy according to Novak, was recorded by Davenport in 1703, who discovered the condition at autopsy.

Fig 2 Photograph of lithopedion. The mass weighed 2 pounds and 10 ounces and measured 15 centimeters in length, 10 centimeters in width and 7.5 centimeters in depth.

Neugebauer in two exhaustive contributions collected 244 cases of combined intra uterine and extra uterine gestation occurring in a period of more than 200 years (1708 to 1913). Novak found 32 additional cases of combined pregnancy of this type in the literature from 1913 to 1926. With the 2 cases which he personally observed the total reaches 278. In 1927 Bermann reported a pregnancy of 5½ months complicated by extra uterine gestation and dermoid cyst, which brings the total to 279 cases.

A CASE OF ADVANCED INTRA UTERINE PREGNANCY ASSOCIATED WITH ECTOPIC GESTATION OF LONG STANDING

Q. S., colored, age 35 years, registered at the prenatal clinic of the Jefferson Medical College Hospital on November 13, 1931. Her general health had always been good. She gave no history of previous operations. The menstrual epoch commenced at the age of 15; the cycle was of the 28 day type and was always normal. The last normal period occurred in the "middle" of May 1931.

The patient had had two full term normal pregnancies, and the children were recorded as being 11 and 13 years of age respectively. There was no history of missed periods or abortions. She felt well throughout the period of gestation and did not manifest symptoms of any kind.

Examination in the antenatal clinic revealed a fairly well developed colored woman exhibiting all the physical signs of pregnancy. The abdomen was enlarged to the size of a 7½ months gestation. In the right side of the abdomen, on a level with the umbilicus, a large mass, the size of a grapefruit, was felt. The tumor was not tender and on palpation it imparted a crackling sensation. The mass seemed to be external to the enlarged uterus and separate from it.

Fig 3 Roentgenogram of lithopedion after its removal.

The patient was admitted to the maternity ward for radiologic examination and further study.

Laboratory findings. Wassermann and Kahn tests were negative. The blood count showed red blood cells, 3,750,000; white blood cells, 8,000; hemoglobin 70 per cent. Urinalysis was negative, except for 30 to 40 white blood cells, per low power field.

Roentgenological findings. Pycnography was included in the roentgen examination because of the presence of many leucocytes in the urine. Radiographic examination disclosed that the right renal pelvis and calyces filled normally with sodium iodide and that structurally the kidney was normal. The skeletal outlines of two fetuses could readily be made out. The fetus occupying the left side of the abdomen was viable, whereas the one on the right side showed overlapping of the cranial bones and apparently had been dead for some time. The head of the living fetus was directed toward the maternal pelvis, the back to the left of the maternal spine and anteriorly (L.O.A.). There was no evidence of disproportion between this fetus and the maternal pelvis. The fetus in the right half of the abdomen was encapsulated and much smaller than the viable one (Fig. 1).

The ureteral catheter was deviated slightly to the right in the pelvis, due to the presence of the fetal head. It passed up the ureter between the non-viable fetus and the viable one.

The plates of the skull of the non viable fetus showed extreme overlapping, indicating that it probably had died at least several months previously. On palpation over the right half of the abdomen, there was an area of crepitation coinciding with the skull of the dead fetus. The crepitation seemed to be associated with the motion of the fetus on palpation.

The non-viable fetus was believed to be extra-uterine because the outline of the shadow of the uterus could be

seen, while that of the fetus fell to the right of it. There seemed to be considerable calcification of the membrane around the fetus.

From the radiographic findings the following diagnosis was made: Intra-uterine pregnancy (L.O.A.) extra-uterine pregnancy with dead fetus (Lithopedion).

Treatment. On December 3, 1931 a laparotomy was performed under general anesthesia. An encapsulated tumor about the size of a grapefruit (Fig. 2) which sprang from the right tube and was bound down to the cecum, was found. It was removed together with the tube and ovary. On the third day following the operation after a short, easy labor the patient delivered a stillborn, premature fetus spontaneously. Convalescence was entirely uneventful, the abdominal incision healing by primary union. Patient discharged in good condition December 23.

Description of lithopedion. The hard irregular mass (Fig. 3) weighing 3 pounds and 10 ounces, measures 5 centimeters in length, 6 centimeters in width, and 3 centimeters in depth. It is completely enveloped by a thick, gray, fibrous capsule to which a small ovary is attached. In several areas the skeletal structure can be distinctly palpated and the forms of the extremities are easily discernible through the sac. The hard, fibrous sac enclosing the fetus was probably formed from the amniotic membranes which had become infiltrated with lime salts.

A crackling sensation is imparted by the mass to the fingers and especially by the bony plates of the skull. When the indurated capsule was incised, decomposing bones and tissue protruded. Several small bones had undergone such decomposition that they dropped out when the capsule was incised.

From the appearance of the bones, it would appear that the fetus had reached 7 or 8 months' development before death had taken place. As the specimen was not dissected, it is impossible to state the character of preservation of the innermost contents.

Figure 3 is roentgenogram of lithopedion after removal.

The case of lithopedion described herewith illustrates the importance of careful routine ante-natal examination. Only by such procedure is it possible to minimize the danger of inadvertently overlooking abnormal conditions which ordinarily do not give rise to special subjective symptoms.

ELECTROCOAGULATION OF THE MELANOMA AND ITS DANGERS

PHILIP D. AMADON, M.D. MONROE MICHIGAN

A SERIES of 27 cases of melanoblastoma of the skin was reported a short time ago¹ at which time one was disappointingly impressed with the failure of our existing methods of treatment. The treatment of these melanotic growths by the popular use of the electric needle² disclosed several facts which led to this study. In the series studied those cases treated by electrocoagulation showed a 100 per cent recurrence at the site of the primary with early regional and generalized metastasis in the majority of cases. The untreated melanoblastoma progressed less rapidly to local and general metastasis than those electrocoagulated. The average time for the appearance of regional metastasis in the cases so treated was 5 1/2 months and 11 1/2 months for generalized metastasis.

The term melanoma which specifies the character of the tumor cell containing a variable amount of an iron free pigment, melanin, will be used in an endeavor to show no partiality as to the connective tissue epithelial or endothelial origin of these growths.

The malignant melanoma has its origin as a rule from the nevus cells of pigmented warts and moles. The benign melanoma or pigmented nevus consists essentially of a localized area of pigmented basal cells with the presence of so called 'nevus' cells arranged in groups or columns in the upper corium.

In the study of this problem the following observations were made permitting of possible explanation of the facts and presenting an application to the entire field of electrosurgery of malignancy.

A more complete understanding of the changes taking place may be possible if a review of the mode of metastasis of the malignant melanoblastoma is made. The lymphatics of the skin are collected from very fine capillaries in the epidermis in lymphatic trunks in the fascial planes, which eventually terminate in the regional lymph nodes. It has been shown by Campbell de Morgan and later by Handley that the growth of melanoblastoma occurs first along the lymphatics. Figure 1 demonstrates the mechanical permeation of the lymphatics in the corium *E*, and in the fascial plexus *C* the spread of the tumor cells occurring along the line of least resistance. Handley, after extensive investigation has described

three zones surrounding the primary lesion. Farthest from the lesion in the fascial lymphatic plexus only (Zone I) with no invasion of the surrounding tissues are found the tumor cells entirely within the walls of the lymphatic vessels. Within this zone is an area of inflammatory reaction (Zone II) with perilymphatic leucocytosis and fibrosis due to rupture of distended lymphatics of the fascial plexus with melanotic tumor cells with a retrograde permeation of the subepithelial tributary lymphatics toward the skin, *E* and invasion of the fascia and muscles. Nearest the primary growth is a zone (Zone III) in which all of the permeated lymphatics have become strangulated by the perilymphatic fibrosis incident to the inflammatory reaction set up by the presence of the tumor cell and, as a result, the lymphatics have entirely disappeared thus leaving only isolated large nodules of malignant cells (*H J*) increasing in size and invading the neighboring vessels, both veins and arteries. That blood vessel dissemination occurs secondarily to lymphatic permeation is thus clearly shown. It is seen that the process is entirely mechanical the tumor cells spreading most widely in the larger, deeper lymphatics and invading the corium and epidermis only after the inflammatory process set up by their presence has been sufficient to fibrose and choke the deeper lymphatics.

A group of benign skin lesions was carefully selected in studying the changes taking place in the skin and subcutaneous tissues on electrocoagulation in the hope that while dealing with a benign lesion sufficient changes might be safely observed and application made to the malignant lesions.

A group of senile keratotic lesions were treated with the electric desiccating needle. In this series so treated many of the lesions were surrounded by dilated venules which extended from the lesion for several centimeters in normal tissue. It was in this particular group that the observations were made. Definite changes, visible to the naked eye took place. On application of the desiccating or coagulating needle to the central portion of the lesion, globules and bubbles appeared in the deeper portions and at the periphery. As the process proceeded a venule at the periphery would suddenly dilate to twice its normal size and blanch free from blood, beginning at the proximal end nearest the lesion and extending to its most

Fig. 4 Epidermis with primary melanoma *G R* corium with blood vessels *F* and superficial lymphatics *E*, *C* fascial lymphatic trunk *D* muscle. Zone I is furthest from the primary lesion, the melanotic cells are entirely within fascial plexus *C*. Zone II—fewer melanotic cells are present within fascial plexus perilymphatic leucocytosis *I* and fibrosis of lymphatics, permeation of superficial lymphatics *E* toward epidermis in corium and in muscle. Zone III is nearest the primary lesion. There is complete fibrosis of the fascial lymphatic plexus invasion of vessels *J* with melanotic cells groups of melanotic nodules *H* free in corium and muscle.

W. H. H. H.

Fig. 5 Senile keratotic skin lesion with surrounding visible dilated venules.

distal part. This same phenomenon could be made to occur in each of the peripheral visible venules by continuing the coagulation. In several instances the escaping globules of tissue steam or gas would suddenly fill the venule and express the blood to its distal end only to dilate the vessel to still greater size as the coagulation continued. Figures 2 and 3 illustrate the appearance of the lesion and dilated venules surrounding both before and following electrocoagulation. Thus was demonstrated the mechanical passage of tissue gases, generated by electrocoagulation, into the visible venules surrounding the lesion.

That such a phenomenon occurs not only in the visible venules but also in the deeper vessels and lymphatics can hardly be denied. The application of this observation to the use of the electric needle in the treatment not only of malignant melanoma but to malignancy in general thus becomes appalling.

With the peculiar lymphatic metastasis here before described and so ably demonstrated by Handley, the mechanical passage of the tumor cells along the line of least lymphatic resistance and secondarily by direct extension into the blood stream the result of electrocoagulation can be readily appreciated. The tissue gas bubbles generated during the process, which are forced under apparent pressure into the surrounding lymphatics and vessels, carry before them the unstable malignant cells which without this assistance are already passing widely along the lymphatics and thus force the invasion to even greater dimensions.

In referring to Figure 1 in which the three zones surrounding the skin lesion are demonstrated it is seen that the malignant cells are farthest removed from the primary lesion in the fascial lymphatic trunk *C*. Actually to state the actual dimensions of Zones I, II, and III and with any

degree of certainty determine the definite extent of progress in the fascial plexus of Zone I is impossible because of the varying grades of malignancy, duration, and treatment.

In reviewing the cases treated by electrocoagulation, one is confronted with a large number in which the skin lesion itself has been attacked. In another group the electric needle has first been passed through apparently healthy tissue at varying distances from the primary lesion completely encircling the lesion before its actual coagulation. The explanation of the second procedure being to seal off the lymphatics before attacking the primary. In both groups the recurrence was 100 per cent.

An explanation of the same degree of recurrence in the group in which the lesion is first completely encircled through apparently healthy tissue is now possible of explanation. Although the process has been carried through apparently healthy tissue on the basis of being wide of visible superficial lesion the malignant cells are present in the fascial plexus at greater distances, even in many instances to the nearest group of lymph nodes. While the lesion is being surrounded by the needle the tissue gas is generated in exactly the same manner as in coagulating the primary lesion and when the fascial plexus is encountered the bubbles escape into that avenue and force before them the malignant cells present to an even wider extent.

Reference to Figure 4 again illustrates the three zones surrounding the primary growth. Figure 4 illustrates diagrammatically what occurs by the generated tissue gas in forcing the malignant cells wider when the lesion is encircled through apparently healthy tissue.

Thus far the discussion has dealt only with the treatment by electrocoagulation of those mel-

Fig. 3. Senile keratotic lesion seen in Figure 2 following electrocoagulation, demonstrating the dilatation of the venules by tissue steam.

anoma which are known to be malignant. That a sufficiently large group of benign melanoma of the skin exist which show malignant change following treatment with the electric needle is not denied although the difficulties arising in determining the actual percentage is wellnigh impossible. Of the 27 cases in this series, the mole was present in 21. In a previous paper the writer endeavored to show that moles, birthmarks and warts of congenital origin may remain benign and unnoticed for years only to undergo malignant changes later, thus presupposing an exciting factor. Undoubtedly this factor in the majority of cases arises as chronic irritation. Some writers regard the melanin pigment in the light of a chemical irritant which may first produce an abnormal epidermal cell proliferation. Borst and others hold that it is set free in the tissue spaces and initiates a malignant proliferation in the endothelial and connective tissue cells. That the presence of a congenital nevus or birth mark is not essential in the production of a malignant melanoma is evidenced by the reported cases of the development of malignant melanoma arising in the puncture wounds, e.g. from a thorn in the foot, especially in the races of the upper Nile. The writer reported a case of malignant melanoma arising in the puncture wound on the leg of a paper hanger as a result of pricking the leg with the points of his scissors carried at the side. Handley explains this as being due to the traumatic implantation into the subcutaneous tissue of a group of dermal connective tissue cells of actual or potential chromatophores.

It seems reasonable to conclude that the improper coagulation of benign skin lesions with the electric needle acts not only as an acute irritant

Fig. 4. 1. Site of electrocoagulation by encircling primary growth. B subfascial lymphatics containing no tumor cells. C fascial lymphatic containing tumor cells in Zone II. D fascial lymphatics dilated with tissue gas from electrocoagulation. E, tumor cells forced by pressure of tissue gas in fascial lymphatics.

in stimulating cells to malignant change but also sets free the abundant melanin present in the tissue spaces where it acts as a chemical irritant according to Borst and traumatically implants into the subcutaneous tissue the actual chromatophores according to Handley thus causing malignant change.

Until some future time when a better method of treatment for this most malignant of diseases is advanced surgical excision with due respect to the anatomical disposition of the lymphatics and thorough knowledge of the spread of the neoplastic cells should remain the procedure of choice. A wide circular or elliptical incision should be made through healthy tissue far removed from the primary growth. The surrounding skin should be elevated or undercut as far as possible and the subcutaneous fat and fascia incised at the extreme base of the undercut skin in a circular manner down to the underlying muscle. The entire mass of primary growth, subcutaneous fat and fascia, with a thin portion of underlying muscle is then removed by a sharp dissection. Greater assurance is then obtained by removing the gland draining area in the same as described fashion.

SUMMARY

1. The cases of malignant melanoma in a series of 27 cases treated with the electric needle showed a 100 per cent recurrence.

2. Electrocoagulation of a group of senile keratotic lesions demonstrated the escape of tissue gas into the peripheral visible venules under pressure.

3. An application of this discovery to electrocoagulation of malignant melanoma renders plausible the explanation of high recurrence on the basis of the mechanical forcing of unstable malignant cells more widely into the tissues by pressure exerted in the lymphatics and vessels by generated "tissue gas."

4. Preliminary encircling of the primary growth with the electric needle through apparently healthy tissue is unsound as the fascial lymphatics wide of the primary lesion may be filled with tumor cells the same phenomenon of generated "tissue gas" pressure occurring here with similar results.

5. Inefficient treatment of benign skin lesions, especially the benign melanoma with the electric needle may initiate malignant change by acting

as an irritant or by the implantation of potential chromatophores into the subcutaneous tissue.

6. Surgical excision of these lesions with special reference to the anatomy and mode of metastasis, remains the procedure of choice.

A CONTINUOUS FIGURE-OF-EIGHT SUTURE FOR MUSCULAR AND PERITONEAL APPROXIMATION IN CÆSAREAN SECTION

FREDERICK C. IRVING M.D., F.A.C.S. BOSTON, MASSACHUSETTS

WHEN closing the uterine wound in cesarean section practically all operators use first a continuous stitch which unites the innermost fibers of the muscularis and avoids the mucosa. This suture line is shown in Figure 1. The closure of the remainder of the uterine wall so as to secure accurate coaptation and hæmorrhage without constriction of tissue has always been a problem. The difficulty is increased when the uterine wall is unusually thick. I have in the past employed for this purpose one or more layers of interrupted single, or of continuous or single figure-of-eight sutures according to the nature of the case. It has been found however that none of these methods was ideal or that none would produce even approximately the desired effect in every case. To overcome these objections I have of late been using a continuous figure-of-eight suture which seems to solve the difficulty in a satisfactory manner. It unites at the same time the middle portion of the muscularis and the superficial muscle fibers along with the serosa and secures good approximation and hæmorrhage. Because of the length of the suture, which makes for elasticity and the absence of knots except at the two ends there is no constriction of tissue.

While designed primarily for the classical cesarean section it may be used equally well in closing a vertical incision in the lower segment. In the latter case one begins at the lower angle of the wound where the uterine wall is thin with an over and over stitch which is continued upward until the thicker portion is reached when the figure-of-eight is begun.

Three-quarters of a length of chromic catgut is threaded on a round pointed curved needle but is not tied in or rethreaded. Beginning at one angle of the wound the suture is passed through the intermediate zone of the muscularis on either side and tied thus anchoring the stitch. The needle is then reversed in the needle holder and passed from within the wound outward on one side through the superficial muscularis and peritoneum. Still keeping the needle reversed the suture is passed through the peritoneum and superficial muscularis of the opposite side into the wound. As the stitch is tightened, it closes the peritoneum and buries the first knot. The needle is then placed in the usual position in the needle holder. Bites are taken in the deeper portions of the muscularis as before the needle is again reversed and the outer portion of the wound united.

Fig. 4. The suture has been cut, the end dropped into the wound, and final knot buried.

as described (Fig. 2) These maneuvers are continued until the last deep stitch has been taken and the final superficial loop is about to be placed. At this point as the needle is passed from within outward the assistant grasps the free end of cat gut and draws it taut. The needle is then passed from without inward, making the last superficial stitch one of double suture material (Fig. 3) The

suture is now tied and cut and its end falls into the wound leaving the final knot also buried (Fig. 4)

Although I have seen no reference to this method of suture it is possible that it has been used and described before. Should that be the case I would gladly surrender priority to anyone who wishes to claim it.

BRANCHIAL AND THYROGLOSSAL DUCT CYSTS AND FISTULAS IN CHILDREN

CONRAD J. BAUMGARTNER, M.D. LOS ANGELES, CALIFORNIA

From the Children's Hospital, Los Angeles

THE clinical picture of branchial and thyroglossal duct cysts and fistulas is frequently unrecognized. Particularly is this true in children when the cysts and fistulas are so often mistaken for abscesses or broken-down lymph glands, and are repeatedly incised and drained without effecting a cure. Although many are not manifest until later years, probably the greater majority of branchial and thyroglossal duct fistulas and cysts that do occur in children are not properly treated until adult life.

EMBRYOLOGY

Noteworthy studies of the embryology of the branchial apparatus have been made by Rathke, His, Born, and others. Undoubtedly the greatest single contribution is that of Wenglowski who in 1913 published a monograph in which he gave the findings of detailed study of serial sections of a large number of human embryos beginning with 3 millimeters and ending with 49 millimeters. I shall first briefly outline the embryology according to Wenglowski and then deal with the clinical side of the subjects.

During the second week of embryonic life certain changes take place in the fetal foregut (Fig. 1). From the interior lateral walls of entoderm five outpouchings or diverticula appear. These are called pharyngeal pouches. Simultaneously the external ectoderm becomes indented over the corresponding pharyngeal pouches. These are the branchial or outer pharyngeal grooves. As the small grooves approach the pouches, the mesoderm is pushed aside so that for a time ectoderm and entoderm come into contact. The contacting areas are the closing membranes which in gill-bearing animals disappear forming the gill clefts,

opening from the pharynx to the exterior. Such perforation of course does not normally occur in birds and mammals.

The grooves and pouches thus formed, separate a series of rounded bars of mesoderm which has been pushed aside by them. There are termed branchial or visceral arches, of which there are 6 all meeting ventrally in the midline of the neck. In each arch there is developed a cartilaginous bar consisting of a right and left half and in each bar also is the anlage of one of the primitive aortic arches.

The first arch is called the *mandibular arch*, and from it are developed the lower lip, the mandible, the muscles of mastication and the anterior part of the tongue. Its cartilaginous bar forms the *focus*, *mallex*, and a portion of the mandible.

The second is the *hyoid arch*. It gives origin to the structures of the upper part of the neck. From its cartilage are developed the *styloid process*, *stylohyoid ligament*, and *lesser cornu of the hyoid bone*. The first two arches grow more rapidly than the remainder so that the latter four become telescoped, the first two arches leaving a deep depression, the *cervical sinus*. (Wenglowski claims that the third arch telescopes to form the *sinus*.) The ventral ends of the second along with those of the third arch, assist in formation of the body of the hyoid bone and the posterior part of the tongue. The third arch assists in the formation of the sides of the neck and its cartilage gives origin to the greater cornu of the hyoid. The fourth and fifth arches also assist in forming the sides of the neck, while the ventral portions of their cartilages unite to form the *thyroid cartilage*. The sixth arch gives origin to the *cricoid*, *arytenoid*, and *tracheal cartilage*.

From the first external indentation, the first branchial groove arise portions of the auricle and external acoustic meatus while of the second third and fourth grooves no traces persist

From the first internal outpouching first branchial pouch, are formed the auditory tube and tympanic cavity the tympanic membrane arising directly from the closing membrane between the first and second arch. In the second pouch lies the anlage of the tonsil. Wenglowski demonstrated that from the third pouch on either side a small duct the thymic duct, descends into the mediastinum to form the thymus. This duct passes in the general direction of the sternomastoid muscle laterally to the thyroid and is lined with squamous epithelium surrounded by lymphocytes. He likewise demonstrated remnants of this tubule in adult necropsy dissections. From the fourth pouch a comparatively short tubule passes on either side in a somewhat medial direction to form the lateral lobes of the thyroid. The parathyroids likewise originate in this pouch. The fifth pouch gives origin to the ultimobranchial bodies which although enveloped by thyroid tissue leave no identity in the human adult.

During the third week a rounded swelling or bud appears on the ventral side of the foregut just behind the first arch. This is the tuberculum impar which along with two similar swellings appearing laterally form the anlage of the buccal part of the tongue. A V shaped swelling arising somewhat posteriorly is called the copula and is the anlage of the posterior part of the tongue. In the fourth week a diverticulum descends between the tuberculum impar and copula and passes as a tubular duct downward anteriorly to the trachea to form the middle lobe of the thyroid gland. The point of descent remains as a depression at the base of the adult tongue which is known as the foramen caecum. The tubular structure is the thyroglossal duct. It later atrophies and is obliterated but occasionally remains patent, producing the congenital anomaly thyroglossal duct cyst or fistula.

BRANCHIAL CYSTS AND FISTULAS

There are several theories regarding the evolution of branchial cysts and fistulas. (1) That they are caused by a vestigial remains of the branchial grooves or pouches. (2) That they are a result of an embryonic perforation of the closing membranes. (3) That they are a persistence of the cervical sinus formed by the telescoping of the rapidly growing first and second arches over the remaining arches. (4) That they are due to a remains of the thymic duct which descends from

the third pharyngeal pouch as demonstrated by Wenglowski in 1913.

Clinical features. A distinction is frequently made between branchial cysts and fistulas and each spoken of as a distinct entity. It appears however that they are all simply a sinus tract which forms a cyst when the drainage is inadequate or obliterated. The lining of both cysts and fistulas consists of squamous epithelium surrounded by a cover of lymphoid tissue.

According to E. Wyllys Andrews, there are five types of branchial cysts or fistulas: (1) complete branchial fistula with internal and external opening (2) incomplete external fistula no internal opening (3) incomplete internal fistula no external opening (4) branchial cysts no internal or external opening (5) branchial dermoid.

The surgical records of the Childrens Hospital show only 4 cases of branchial cysts and fistulas. This is however not a true index of the incidence of this anomaly. In 1929 Hyndman and Light reviewed a series of 90 cysts and fistulas. In their series the average age of onset was 17 years and the condition was noticed at birth in only 21 per cent, and only 11 occurred before the age of 11 years which is the age limit of admission at the Childrens Hospital. The ages of these 4 children were 2 2 3 and 9 years, respectively. There were 2 each girls and boys. The sides of the neck involved were likewise equally represented. The age of onset of these children was, at birth at 2 months at 18 months and at 7 years. In the cases reviewed by Hyndman and Light, 53 occurred in females and 47 in males and of the 28 cysts 35.5 per cent were on the right side and 64.5 per cent on the left, while of the 62 fistulas, 51.8 per cent were on the right, 31.4 per cent on

Fig. 2. left. Branchial cyst which developed after infection of fistulous tract

Fig. 3. Branchial fistula, showing small opening on the left side at about the middle third of the sternomastoid.

the left, and 16.8 per cent were bilateral. Multiple openings occurring on 1 side are indeed, rare. There is but one reported by Virchow in 1861. Familial tendency is likewise not the rule, but again scattered cases have been reported. In Virchow's report of 1861 there is the occurrence in a mother and 8 children, and 2 other cases of family tendency; and in the 1929 study of Hyndman and Light they reported cases in which the mother and 3 of her 5 children presented fistulas.

Clinically a branchial cyst usually manifests itself simply as a uniform painless, nontranslucent semifixed fluctuant tumor which is never tender except from pressure or secondary infection (Fig. 2). Ordinarily its presence does not cause the child any particular discomfort. There have, however, been reports of serious trouble caused by pressure on neighboring structures, particularly difficulty in breathing or swallowing. Thomson of England reported a branchial cyst which produced hoarseness and was accompanied by a fixed vocal cord. When the swelling was at its height, there was dysphagia and cough with complete misery of his patient. At exploration, the cyst was found attached to the larynx and passed to the lateral wall of the pharynx. The symptoms completely subsided after excision of the cyst. A branchial cyst has a uniformly characteristic position along the anterior border of the sternomastoid and extends under it to the deeper structures of the neck. The size depends upon the amount of drainage or secretion present and may vary from a centimeter in diameter to almost fill

ing the entire side of the neck. The average size, however, is about that of a walnut.

The clinical picture of branchial fistula is that of a sinus which periodically drains a mucoid or thin milky material which may be associated with a cyst, depending upon adequacy of drainage. The fistula is also not prone to give any serious trouble in the average case except that the discharge is annoying to both parent and patient and the fistulous tract often stops drainage for a time with the production of a cyst which again periodically empties itself.

Not infrequently however repeated secondary infections do take place with an occasional serious cellulitis of the neck. Also some very aggravating conditions have been observed. A case reported by Louis Carp in 1926 is that of a boy 5 years of age who, with a branchial fistula gave a history of an unproductive cough of 2 years duration which was unsuccessfully treated by tonsillectomy and medical measures. At exploration an incomplete fistulous tract was found adherent to the vagus nerve. Excision of the tract brought about relief of all symptoms which were as the author stated quite surely due to vagal irritation. It is known that probing or pinching a tract has produced vagal symptoms such as cough, palpitation, intermittent pulse, hoarseness, pallor and sweating. I have had occasion to operate on an 18 months old child whose mother said the baby had had asthmatic attacks whenever the fistulous tract stopped draining and became distended. This appeared to be undoubtedly a case similar to that reported by Carp. Furthermore, at operation

a distinct nerve fiber was found attached to the tract extending deep to the carotid sheath apparently leading to the vagus nerve. The child has however had several mild attacks since and has been found sensitive to milk.

The fistulous opening may be situated at any level of the neck but is constantly and without variation just anterior to the sternomastoid muscle (Fig. 3). There is sometimes an area of pigmentation about the opening and occasionally a thickened bit of tissue may be felt which contains a bit of cartilage and is called the cervical auricle. The fistulous tract almost invariably runs upward and backward beneath the anterior portion of the sternomastoid muscle. It passes over the carotid sheath to the midportion of the posterior belly of the digastric muscle whence it arches medially behind the stylopharyngeus muscle to the tonsillar fossa. By tugging at the skin over the opening one can often feel the cord like structure extend ing under the sternomastoid.

Bearing in mind the close relationship that exists between the anatomy and histology of branchial fistulas and the embryology of the thymic duct one must readily agree with Wenglowski that the origin of this condition must be attributed to vestigial remains of the thymic duct. Contradicting this theory some authors argue that one occasionally sees a fistulous opening in the region of the ear which is above the level of the third pouch. These are probably either secondary to infection or in most cases are rudimentary external ear canals from the first groove.

With the typical clinical picture a diagnosis is usually comparatively easy. As a further aid in diagnosis, Hamilton Bailey in 1922 demonstrated the presence of cholesterol crystals on microscopic examination of aspirated content in some cases. Wangenstein gives a further aid to differential diagnosis by X ray examination suggesting aspiration through a needle and injection of a medium opaque to the X ray (Fig. 4).

Differential diagnosis must be made from inflammatory and tuberculous adenitis, hygroma, thyroglossal duct, hemangioma, and lipoma.

Inflammatory adenitis is often bilateral and numerous glands are involved. They are tender and the offending focus usually can be found in sore throats, tonsils and teeth. Tuberculous glands may be more readily confused with cyst and fistula but they are firm and tender and other glands usually are involved and often matted together in a group. The discharge from the fistula in broken down glands is purulent while in branchial fistula it is clear mucoid or milky and may contain cholesterol crystals.

Fig. 4. Branchial fistula, lipiodol injection showing characteristic extension beneath sternomastoid to middle portion of the posterior belly of the digastric muscle where it arches medially to the tonsillar fossa.

Cystic hygroma is translucent, occurs most frequently in the supraclavicular area, is often lobulated and may grow to enormous proportions extending up into the face in front of the ear.

The thyroglossal duct occurs invariably in the midline and moves up on swallowing.

Hemangiomas decrease in size on pressure and have the typical discoloration.

Lipomas are lobulated, soft, and non fluctuatory.

TREATMENT

Frequent incision and drainage is often the lot of these children before the condition is recognized and properly treated. Two of our 4 children had incision and drainage without benefit before entering hospital. Only complete surgical removal under general anesthesia will effect a cure.

The extent of the sinus tract should be roughly determined before operation by injection of an opaque medium and X ray (Fig. 4). Visualization of the tract may be facilitated by a simple method described by R. J. McNeill Love. A horse hair or dermal pursestring suture is placed about the fistulous opening and drawn taut to shut off secretion. In a few days the tract becomes distended and identification is then comparatively easy.

The injection of methyl blue as ordinarily carried out, is usually a messy job. As the tract is

Fig. 5. Incision of bronchial fistula showing armamentarium and method of massaging methyl blue into the tract.

opened somewhere in the course of dissection, the dye spills, stains all the surrounding tissue and all identification is lost. I have however found methyl blue to be a distinct aid when used in the following manner (Fig. 5).

The end of an ordinary hypodermic needle is broken and rounded off the caliber of the needle depending upon the size of the fistulous opening. The direction of the tract is determined with a probe and the methyl blue then injected with the use of the blunted needle. Too great a pressure may rupture the tract and defeat the purpose of the injection. At the same time the fingers of the left hand gently massage the neck to and fro in the direction of the tract. Thus the epithelium in even the minutest diameter of the tubule may be reached and stained. Using the same syringe and needle we then gently but thoroughly wash out the methyl blue with water or saline alternately massaging outwardly until the return is only

Fig. 6. Incision of bronchial fistula, showing assistant's finger pushing outward in the region of the tonsillar fossa, as dissection is carried to the pharynx.

faintly stained. In this manner the epithelial lining remains stained and if the tract is load vertically opened during the dissection no soiling of the neighboring structures will take place.

A small probe is again inserted and the incision made through skin and platysma along the anterior border of the sternomastoid and surrounding the fistulous opening. The platysma is reflected laterally on both sides, and the sinus is dissected to the pharynx in its entirety. The stump may be dealt with by several methods as recently described by Herbert Willy Meyer. By the method of von Hackerer a probe is passed through the lumen of the duct into the pharynx, and with a suture the stump is attached to the probe and inverted into the mouth cavity and there tied and cut. By the method of Koenig a probe is forced into the pharynx a short distance from the duct which is then sutured and pulled with the probe into the pharynx, thus re-implanting it. The method of von Hackerer appears most desirable for several reasons: there is not the possibility of hemorrhage from passage of the probe there is not the danger of opening of fresh avenue of infection from the mouth and chiefly it does away with the entire tract. Minute tubules would however be rather difficult to invert.

I have found that dissection of the stump may be carried to the pharynx by simply having an assistant place a finger in the tonsillar fossa

Fig. 7 (left). Thyroglossal cyst occurring at the level of the hyoid bone.

Fig. 8. Thyroglossal duct fistula, showing characteristic midline opening.

(Fig. 6) By having him push outward the stump is cored out until it approaches the finger of the assistant when it is severed and touched with tincture of iodine. A small split tube is inserted for drainage for 24 hours and closure made in the usual manner.

THYROGLOSSAL DUCT

The development of thyroglossal duct cysts and fistulas is definitely established as being the result of a failure of the embryonic thyroglossal duct to become obliterated.

Clinical features. The condition is more common than branchial cysts and fistulas. At the Childrens Hospital there were 11 children who came to surgery for thyroglossal duct excision. Of these 6 were boys and 5 were girls. One was a negro boy, 2 were Mexican, 1 Italian and the others of American families. The ages ranged from 2 to 11 years of age. In 1925 Klingenstein and Colp received 42 cases of thyroglossal ducts and in their series 31 were males and 11 females. Twenty-one occurred in the first decade, 10 in the second, 7 in the third and so on. The oldest age at which the lesion was discovered was 35 years, the youngest, of course at birth, of which there were 5. In the Childrens Hospital series the onset at birth occurred in two instances. In the remainder the age of onset was at 6 months, 18 months, 2, 3, 3, 6, 8, 9 and 11 years, respectively. Adequacy of drainage decides whether a cyst or

fistula is formed. In the series of Colp and Klingenstein there were 13 cysts, 20 fistulas and a combination in 9 cases. In this series 3 were simple cysts, only 1 a simple sinus and the remainder were fistulas which were associated with cystic formation.

The cyst may appear at any level from the foramen cecum to the suprasternal notch and the corresponding fistula may make its exit anywhere from the chin at the floor of the mouth to the suprasternal notch. It is rarely however that it appears above the hyoid. The majority of fistulas open below the hyoid and considerably higher than the suprasternal notch. All are invariably in the midline and may vary in size from a pea to a lemon (Fig. 7).

The clinical picture of the cyst is that of a painless, soft, fluctuatory, semifixed mass occurring in the midline of the neck and moving up on swallowing. With a fistulous opening there is either a continuous or intermittent drainage of a clear or milky solution (Fig. 8). Troublesome symptoms such as a choking sensation, difficulty in swallowing and obstructive dyspnea are rare, but secondary infection either ascending from the external opening or descending from the foramen cecum is fairly common. With infection the process usually remains localized and discharges through the sinus opening, although occasionally a severe cellulitis of the neck develops. All too frequently the simple non-infected cyst is mistaken

Fig. 9. Excision of thyroglossal duct fistula. The platysma muscle has been reflected and dissection carried to the hyoid bone.

for an abscess, and consequently a history of repeated incision and drainage without cure is obtained. Two of our children had thus been treated in one of which a later attempt at removal had been undertaken and in 2 other children removal had been previously attempted but the operation had been without success in affecting a cure.

The sinus tract may pass over through or beneath the hyoid to the base of the tongue. The larger tract may be felt as a distinct tubule lying over the trachea and moving on swallowing. The

Fig. 10. Excision of thyroglossal duct fistula. The mid-portion of the hyoid bone has been removed. From this point the tract is corded out in the direction of the foramen cecum, which is at about a 45 degree angle with the patient in the goller position. Dissection is carried up to a point where the finger at the foramen cecum can be identified (Sistrunk).

Fig. 11. Excision of thyroglossal duct fistula. The mid-portion of the hyoid bone is being removed with bone forceps according to the method of Sistrunk.

lining consists of squamous epithelium surrounded by lymphoid tissue.

Differential diagnosis must be made from ranula adenitis, pyramidal lobe of the thyroid, and the branchial cleft anomalies.

Ranula of the sublingual gland occurs in the anterior part of the floor of the mouth and can be seen as a bluish cyst under the floor at the anterior part of the tongue and does not move on swallowing.

Adenitis, either single or tuberculous, occurring in the midline of the neck, is rare indeed and is associated with other tender glands. Movement on swallowing does not take place.

A pyramidal lobe is attached to the thyroid near the isthmus. It is practically never enlarged unless it is associated with a goiter and it does not fluctuate.

TREATMENT

As in branchial cysts and fistulas, complete excision under general anesthesia is the only cure. The fistulous tract should be stained according to the method described in treatment of branchial tracts.

W. E. Sistrunk has described a highly satisfactory method of removal and his is the technique I shall here describe.

A horizontal incision about 1 1/4 inches long is made through skin and platysma and surrounding the sinus opening. The flaps are reflected and the dissection of the tract carried to the hyoid bone (Fig. 9). The sinus may pass over through

or beneath the hyoid bone to the foramen cæcum at the base of the tongue. Beyond the hyoid the tract frequently assumes minute proportions. To facilitate further removal a section of the mid portion of the hyoid is removed with bone cutting forceps (Fig. 10). An imaginary line is pictured from the hyoid to the middle of the base of the tongue. This is about at a 45 degree angle with the patient in a goiter position on the operating table. Dissection is carried further in the exact direction of the foramen cæcum. To orient himself and to aid the dissection the surgeon places a second sterile glove and sleeve over the left hand. The index finger is placed in the mouth of the patient at the foramen cæcum and pushed out toward the hyoid bone. At the same time the fistulous tract is cored out to the base of the tongue (Fig. 11). A split tube drain is inserted. The cut ends of the hyoid approximated. The platysma is then sutured with interrupted plain No. 00 catgut and the skin closed in the usual manner.

REACTIONS AFTER INTRAVENOUS INFUSIONS

A FURTHER REPORT ON THEIR ELIMINATION¹

LEE RADLJAKOFF, M.D. PHILADELPHIA

IN a previous report, the causative factors of reactions after intravenous infusions and the theoretical elimination of these reactions were discussed. Since that time Perkins has summarized the more recent literature and has discussed the subject in a very thorough way. It is the purpose of this contribution to discuss our practical experience in applying the principles developed in our previous report.

When beginning a study of intravenous solutions, an evident lack of organization and method of preparing solutions was evident in our hospital. Solutions were prepared in individual dressing rooms from bottles of commercial distilled water many of which had been standing unused for months. Glassware was merely rinsed, and a commercial and impure glucose was used in the preparation of the solutions. The majority of glucose used came from ampuls of 50 per cent glucose from various manufacturers, being diluted with saline solution prepared in the hospital. Solutions of uncertain age were used oftentimes a month old due to the fact that flasks were labeled only on the initiative of the individual dressing room nurse. Needles were often rusty—tubing was prepared by boiling in a water sterilizer containing from 10 to 40 grains of bicarbonate in 3 gallons of water. From the standpoint of our later experiences it seems queer that an infusion could ever have been given under these circumstances without an accompanying reaction. Later a Barnstead single still was used, the water being distributed in bottles and again kept in dressing rooms for various intervals. This naturally gave no improvement.

When our new distillation apparatus was installed the first measure applied to correct all these evils was to install a central supply room all solutions being prepared by one individual and delivered to wards and floors as requested. Later we found that even the shifting personnel of student nurses would not suffice because of interference with the work by other duties, and a graduate nurse was put in charge of all solutions. It is also advisable where possible to have all equipment for the administration of intravenous fluids taken care of in one central supply room, but this change we have not been able to effect here.

To apply the theories developed in our earlier work we applied first to the Barnstead Still and Sterilizer Company to design for us a suitable distillation apparatus. The still designed by them is of the *continuous distillation* type with horizontal condenser. Multiple baffle plates were placed in the upper portion of the still and a smaller set in the vertical portion of 3 inch pipe to the condenser. This system forces the steam to turn many angles, striking against numerous plates, thus losing its spray. In addition to this a deconcentrator tube as described by Severinghaus was attached. This consists of a $\frac{1}{4}$ inch brass pipe introduced through the bottom of the still and attached to the waste pipe by a valve and with an air vent. The tube rises vertically in the center of the reservoir about one third of its height. The level of water is kept about one-half inch above the open end of the tube. When the valve is open the surface of the water is constantly in motion toward its center which greatly diminishes the formation of spray. Increased concentration at the surface which is another cause of spray formation, is also prevented by this tube. Other satisfactory distilling sets were on the market, especially the double and triple distillation outfits with baffle systems, and although these might be slightly more satisfactory they were more expensive and did not promise to be much more effective in removing pyrogenic material. In the use of this apparatus we soon found it necessary to observe four rules:

1. To distill slowly—this prevents excessive foaming.
2. To distill for 15 minutes into waste this acts to clean out accumulated products.
3. To deconcentrate with sufficient rapidity.
4. To clean entire apparatus regularly every 6 months, removing boiler scale and nitrogenous products.

Failure to observe any of these rules has resulted in reactions.

Since theoretically immediate sterilization should prevent formation of further pyrogen, the water was first distilled into a sterilization tank equipped with cooling coils. As soon as a sufficient amount of water was distilled it was sterilized and allowed to remain in the tank for 24 hours, except as used. We could demonstrate no

gross bacterial growth in this water yet after a week of use reactions began to occur and we found the tank walls covered by a nitrogen containing material. Repeated cleansing failed to keep this tank clean and it was therefore abandoned. A 5 gallon glass tank was employed but this developed the same difficulty so that water has since been distilled into glass graduates and immediately made up into solution. We found that in a warm room a delay of sterilization of as little as 4 hours could generate enough pyrogenic material to produce reactions.

The source of contamination and the point of trouble can easily be located by applying the permanganate test described by Carter to water in each stage of production. The test as described can be further simplified by using 10 cubic centimeters of water for the test and titrating this against two hundredth normal potassium permanganate in a clean test tube heating the water to boiling at intervals. If more than 1 cubic centimeter of permanganate is reduced the water is dangerous and if 5 cubic centimeters is reduced reactions are almost sure to occur. We have found this a very valuable test in locating the source of trouble when reactions occur. With the exception of a few instances when rules for distillation were badly disregarded, the distilled water has never reduced 1 cubic centimeter of the permanganate solution in this test. Obviously if the freshly distilled water is free of contaminant and reactions occur contamination source must be at some place during preparation of solution and by testing each stage the source can be located.

The preparation of the solutions next received our attention. By using the test just described it was found that if glassware was merely rinsed or imperfectly washed pyrogen might accumulate in it by bacterial growth in small residues, even in the moisture lining flasks. Accordingly strict rules were developed for cleansing of all glassware. The flasks and graduates are first washed in tincture of green soap and hot water and rinsed in tap water. The standard cleaning solution of potassium bichromate and sulphuric acid is then used. The glassware is next rinsed four times with tap water and six times with freshly distilled water. It is then ready for use. If not used within 2 hours the entire procedure is repeated.

The chemical ingredient of each solution is added to the graduate of distilled water stirred till dissolved and the resulting solution is then filtered through a fine filter paper. Erlenmeyer flasks of a size twice the capacity of the solution contained are used to prevent splashing during autoclaving.

In previous times ampuls of 50 per cent glucose had been added to the salt solution or to distilled water to prepare the glucose solutions. This appeared to us unsatisfactory fragments of glass from broken ampuls were constantly added to the intravenous solutions with small amounts of alcohol used to sterilize the ampuls externally and too sterility seemed questionable. Moreover each manufacturer claimed various advantages for his products and various staff members preferred different brands of glucose. Mallinckrodt's or Merck anhydrous chemically pure glucose bought in 100 pound lots and made up in our own solutions has proved very satisfactory and has reduced the cost of glucose solutions about 60 per cent. Glucose has been prepared in 5 and 10 per cent concentration. Sodium chloride is used in the usual tablets supplied by various manufacturers. The most used solution has been 5 per cent glucose in normal saline.

While seal with cork and paraffin seemed ideal from the point of view of permanency and completeness objections were raised by members of the hospital staff who insisted that solutions should be no more than 24 hours old. For this reason the conventional seal of gauze cotton and waxed paper has been used. As the use of fresh solutions has necessitated a great deal of waste we have been gradually increasing the length of time solutions may stand after sterilization without producing detrimental results and we hope soon to apply the cork and paraffin seal so that we may keep the solutions 30 days. We find that the longer solutions can be kept the less is the waste and the greater is the economy in labor.

The speed of injections, temperature of solution and amounts administered still persist in many minds as causative factors in producing unfavorable reactions.

Following the principles previously described almost all of our solutions are given at room temperature. Continued venoclysis is given without heatlog save for running the tubing along the patient's arm. We have never seen untoward effects of too cold solutions. Speed of injection has no effect on producing pyrogenic reactions as far as we can determine with the exception of the fact that fewer reactions occur with the use of venoclysis than in rapid intravenous injections. Pyrogenic reactions have, however been observed repeatedly after hypodermoclysis and certainly administration by this method is sufficiently slow.

The amount of solution administered may have a slight bearing. If 1,000 cubic centimeters of solution contains only sufficient pyrogen to cause

a reaction one half that amount should not do so. On the other hand with gross contamination quantities as small as 50 to 100 cubic centimeters can give severe reactions.

In our previous work we were inclined to disbelieve any possible effect of rubber tubing in causing reactions despite the previous work of others. The grounds cited was the boiling of rubber with non-pyrogenic solutions and administration to dogs without reactions. This has been repeated recently with four varieties of new tubing with the same result. Rubber tubing cannot be ruled out entirely on these grounds, however since dogs are relatively insensible to reactions. One of our wards has been especially equipped with an intravenous tubing sold by Becton, Dickinson & Company. This tubing far exceeds ordinary tubing in durability having withstood constant use for over 18 months without replacement. We have noted that although this ward used a great deal of intravenous fluid no reactions have occurred when this tubing was used. In many of the reactions recorded during the past year a history of new rubber tubing could be obtained. One particular instance presents some definite evidence that tubing may be an occasional causative factor.

A patient suffering from peritonitis after a ruptured appendix had received intravenous glucose and salt by venoclysis for 4 days without reaction. At this time the rubber tubing commenced to leak. The tubing was removed and a new set containing new rubber tubing was dropped into the same flask of solution previously in use and reconnected to the cannula in the vein. The patient received less than 50 cubic centimeters when a violent reaction occurred. Here all factors were unchanged except tubing.

Accordingly all our venoclysis sets and intravenous sets have been equipped with special Becton Dickinson & Company tubing and this is further prepared by the Stokes technique, namely filling the tubing with 10 per cent sodium hydroxide for 12 to 24 hours, washing in running water for 2 hours and boiling in distilled water for 1/2 hour before using. Since this was done we have had but 3 reactions from some three thou-

sand liters of solution 2 of which could be definitely traced to the necessity of cleaning the still and all of which were mild. Rubber tubing offers another possible difficulty however in that it is frequently not sufficiently cleaned before using a second time, and contamination of the tubing occurs. This is especially true if a blood transfusion had been previously given. Scrupulous cleanliness and allowing waste of 100 cubic centimeters of solution through the needle before insertion into the vein are safeguards of this possibility.

RESULTS

Previous to the introduction of our new system infusions were sparingly given the clinician balancing always the beneficial effect against the dangers of reaction. The average consumption of intravenous solution was about 40 liters per month and reactions occurred in 30 per cent of these. Since installation of the new system consumption has gradually raised until at present about 600 liters are used per month. Reactions have varied from 4 per cent to none in the various months as we encountered the difficulties described. During the past 2 months one mild reaction has occurred in 1,033 liters of solution used. During the last 3 months our central supply room has taken over the making up of sodium citrate solutions for transfusions, and even here we have noted a great decrease in the number of posttransfusion reactions of pyrogenic type.

The constant rise in consumption of solutions indicates to us an increasing confidence on the part of clinicians in the safety of solutions prepared. A very occasional and mild reaction still occurs, but because of the rarity of these reactions it is extremely difficult to determine their cause. Perhaps individual susceptibility is the final factor over which we naturally have no control.

POSTOPERATIVE SUPRAPUBIC FISTULA

ANALYSIS OF CAUSES

EDWIN BEER M.D., F.A.C.S. NEW YORK

AMONG the annoying and tantalizing complications of suprapubic cystotomy whether done for obstruction of the neck of the bladder or tumor of the bladder is persistent fistulization or delayed healing of the suprapubic bladder incision. At times such incisions fail to heal and there is continuous urinary leakage; in other cases the wound opens and closes with intermittent urinary leakage. Fortunately after a careful study and recognition of the underlying cause most of these patients can be definitely cured and in our experience that has usually been the end result. On the other hand many patients have come to us in whom repeated attempts have been made to close the bladder fistula without satisfactory results.

During the last 20 odd years it has been possible in studying these cases to arrive at a pretty definite understanding as to the underlying causes of delayed closure and repeated re-opening of the suprapubic wound. The causes of this trouble seem to be local in the majority of cases, but in other cases, the trouble appears to be due to disease in the proximal part of the urinary tract, while in others the urinary tract distal to the bladder is the essential factor.

Among the local causes of persistent fistula or recurring fistula of the bladder the most common are connected with faulty technique of the operation whether it be a one step or a two step prostatectomy or a resection of the bladder for neoplasia. As a result either of poor operative technique or of the patient's vomiting and coughing after operation, the bladder wall may prolapse between the rectus muscles with the result that a mucous membrane channel is formed which prevents the bladder from closing. In some cases the mucous membrane channel even grows out through the muscles and unites with the skin making a mucocutaneous fistula. It has been claimed by some that in opening the bladder, unless the incision is made high up near the dome fistulization is liable to occur but in our experience, irrespective of the site of incision whether high or low fistulization seems no more likely to occur with the low incision, than with the high incision in the bladder wall.

Foreign bodies left behind in the bladder either stones or secondary growths, or even real foreign

bodies, which become more or less encrusted with phosphatic material are occasionally found to lead to protracted slow closure of suprapubic wounds. Large diverticula of the bladder which have been overlooked in the course of the operation on the bladder whether for stone or prostatic enlargement, especially if infected are very liable to lead to slow healing of the suprapubic wound and often prevent definitive closure. After the diverticulum is removed just as in the other group after the foreign body is removed the suprapubic wound closes kindly much to the surprise of every one concerned.

In addition to the conditions mentioned small contracted, fibrous bladders are very liable to lead to repeated fistulization of the cystotomy wound and it is wise to avoid giving too good a prognosis in prostatic obstruction cases associated with contracted bladder both as to the cure of the contracted bladder and as to the relief of prostatic symptoms. Although one sees such cases completely relieved at times in most instances the contracted bladder never dilates properly and as the patient's capacity remains small the frequency persists and, unfortunately in these cases, fistulization is liable to be a disagreeable complication. In addition to this type of bladder a cystostomy in the presence of urinary tuberculosis is practically always followed by fistulization unless partial or complete exclusion of the tuberculous focus in the upper tract takes place.

Among the well recognized causes for fistulization of the bladder following cystotomy in the peripheral part of the urinary tract, are persistent obstruction at the neck of the bladder or in the urethra. Overlooked fibrous necks or overlooked prostatic adenoma masses are very liable to keep the suprapubic wound open, and naturally strictures in the urethra, stones in the urethra or other disturbances in the peripheral urinary tract, predispose to this disagreeable complication. These causes are rather well recognized and following transurethral section of the neck of the bladder with the electric cutting current, or dilatation of the stricture at the neck or in the urethra or removal of the stones, the suprapubic fistula usually closes and stays closed permanently after a brief use of an indwelling urethral catheter. In some rare cases neurogenic disturbances may

possibly underlie the delayed closure. In these disharmonies between the detrusor and sphincter muscles, the peripheral obstruction seems the important factor and it is relieved by use of an indwelling urethral catheter.

In the proximal part of the urinary tract, it is not generally appreciated that causes of continued and repeated opening of the bladder wound may be found. Infected calculous pyonephroses or infected hydronephroses, such as are occasionally seen after ureterovesical anastomoses, are not infrequent causes of persistent suprapubic fistula, and in our experience, after removal of such infected and infecting foci from the upper urinary tract either by nephrectomy or by more conservative means, it is surprising to see how frequently the suprapubic fistula will close.

In this brief analysis of the various local, proximal, and peripheral causes of persistent suprapubic fistula one must bear in mind that from the therapeutic standpoint our efforts must be of the simplest character while studying the case and deciding upon the cause of the trouble. Naturally if indwelling catheter with cauterization of the sinus from without and cystoscopically and occasionally irrigations with silver nitrate solution of the bladder will lead to a closure of the fistula. It would be unwise to rush in and do a large secondary operation to remove a diverticulum or to remove a kidney even if it be the site of calculous disease or be an infected hydronephrosis following some procedure on the ureter. If however local

measures, such as have just been mentioned, fail to effect a definite closure of the suprapubic fistula, it may be necessary to do something more radical which may consist of excision of the fistula and inversion of the bladder in mucocutaneous fistulae, or excision of the diverticulum in cases associated with infected diverticulum. In other cases, section of the contracted fibrous neck, etc., and again, in other cases, the removal of the infected and infecting proximal segment, kidney and ureter may be necessary before permanent closure of the fistula is obtained.

SUMMARY

Underlying causes of persistent and recurring suprapubic fistula following cystostomy

A. Local.

1. Improper surgical technique and partial prolapse of the bladder wall between the rectus muscles.

2. Stones, gauze sponges left in bladder

3. Contracted bladder.

4. Overlooked large, infected diverticula.

5. Disharmony between the sphincter and the detrusor muscles.

B. Peripheral.

1. Unrelieved obstruction at the neck of the bladder fibrous necks, adenomata.

2. Strictures, stones, etc. in the urethra.

C. Central.

1. Infected stone kidneys, infected hydronephroses, and tuberculous kidneys.

CORRESPONDENCE

ETIOLOGY OF GASTRIC AND DUODENAL ULCER

To the Editor: I would like to add my own results^{1,2} to the very interesting paper of Warren B. Matthews and Lester R. Dragstedt, in *SURGERY, GYNECOLOGY AND OBSTETRICS*, September 1933, p. 365.

Experimenting on dogs I found that ulcers in the duodenum (with the symptomatology of duodenal ulcer) could be produced in dogs simply by tying the

main pancreatic duct. These ulcers were confirmed by microscopic and histological examination. Melbourne Australia. J. LEON JONA.

JOHN B. MURPHY

Material is being collected for an authorized biography of Dr. John B. Murphy. If any reader of this *JOURNAL* has in his possession letters from Dr. Murphy, knowledge of facts concerning his life or any other data, it would be appreciated if they were sent to the Editors. All material will be returned promptly and the source credited.

CHRONIC ADHESIVE PERICARDITIS

FROM the standpoint of pathology there are three chief conceptions as to chronic adhesive pericarditis. In one there are adhesions between the heart and pericardium and also between the pericardium and surrounding structures especially the chest wall—mediastinopericarditis. In the second the pericarditis is a constricting one and, in the third, the adhesions are found between the outer layer of the pericardium and surrounding structures, especially the pleura, without any involvement of the inner layer of the pericardial sac. This latter condition is common in fibroid phthisis with pleuritis, and in tuberculosis confined chiefly to one lung and pleura thus causing moderate displacement of the heart toward the affected side.

In pulmonary tuberculosis the heart is usually small, either as a result of long rest, or because constricting pericarditis may be due to tuberculosis. This latter condition is rare, however.

The symptoms should make differentiation possible. In the external type of adhesive

tuberculous pericarditis with or without displacement of the heart, even if the shadow is small, there should be no essential cardiac symptoms. In constricting pericarditis, the symptoms are striking engorgement of the veins, chronic passive congestion, ascites and anasarca, together with other symptoms characteristic of broken cardiac compensation. There is this difference however, the heart is not hypertrophied and dilated as it would be if valvular or myocardial disease were present.

There is a widespread belief that suppurative pericarditis, in those patients who survive operation, is apt to be followed by disabling pericardial adhesions. It is natural to assume that drainage of the pericardium is followed by adhesions between the parietal and visceral layers and the leaving of drainage material in the pericardial sac should increase this likelihood. The writer has operated on eleven patients with suppurative pericarditis, with six recoveries. The patients who recovered were children or young adults and all were followed for some time. One the youngest, who was four years old at the time of operation, had a stormy early and late convalescence, for four months there were anasarca and ascites and the peritoneal cavity was tapped several times. For the last several years he has grown normally however, and there has been no clinical evidence of cardiac disability. One patient a nurse in training for about a year after operation, was short of breath on unusual exertion. She was without other signs, however, and is now without symptoms. Another, a six year old child, developed a secondary walling off in the pericardial sac high up and posterior, against

the left auricle which required a second operation. This pocket was located with the X ray and the examining finger introduced along the drain tract in the pericardium encountered fresh adhesions everywhere and was thrust through the wall of solid exudate into the pocket of pus. In spite of this, the child, after a slow convalescence was apparently well in six months and has since grown and behaved in a normal way. Two other patients were young adults and made good recoveries after a period of serious illness immediately following pericardiotomy. The last patient was operated on by a modified approach described elsewhere and made a more rapid recovery than any of the others. It was believed that better drainage was an important factor. He has been seen repeatedly and is not disabled.

One would expect to find after such operations, extensive adhesions between the outer layer of the pericardium and the chest wall and pleura, where these structures form the boundaries of the "triangle of safety" especially if no attempt is made to fasten the edges of the incised pericardium to the subcutaneous tissues. If such adhesions do occur the pathological findings should closely resemble the condition found in the mediastinopericarditis, and the disability resulting would call for the procedure of Brauer.

The pericardium follows the heart closely in its movements. It is easy to understand therefore that, if non-constricting adhesions occur between the two layers of the pericardium no very great handicap may be imposed upon the heart action unless the outer layer of the pericardium is adherent to the surrounding structures and, even then limitation of motion may not be marked unless the surrounding structures are unyielding. It is upon this assumption that the whole procedure of Brauer is based.

In my own experiences I have been surprised that pus escaping from the incision in the pericardium has not percolated into the middle mediastinum between the two pleura and the pericardium, or even into the posterior mediastinum, as the potential space between the two edges of the pleura just behind the sternum and in front of the pericardium (the "triangle of safety") is continuous with the middle and posterior mediastinum unless shut off by adhesions between the pericardium and pleura. There has been very little evidence that such an extension of infection has occurred, and no patient has as yet, presented any of the symptoms and signs associated with chronic adhesive mediastinopericarditis. I am quite sure that the outer layer of the pericardium does become to some extent adherent to the structures surrounding it, but I have not observed any evidence that there are adhesions between the pericardium and the unyielding bony and cartilaginous chest wall. It is certain that some individuals with rheumatic pericarditis develop widespread and dense adhesions between the heart and pericardium between the pericardium and surrounding soft parts and between these structures and the chest wall. Pericardiotomy with an open and discharging drain tract is bound to be followed by extensive infection. Just why dense and widespread adhesions are apparently not present as a postoperative complication is not at all clear.

One factor however, may explain much. The patients who recovered had suppurative pericarditis uncomplicated by empyema and, in most instances, the infecting organism was the pneumococcus. In the peritoneum and in the meninges, the pneumococcus causes a very fatal infection, but, in the pleura and in the pericardium, this infection is relatively less destructive of life. ARTHUR M. SHIPLEY.

THE CHANGING TREND IN SURGICAL TECHNIQUE

IT is almost impossible for the busy worker in his generation to evaluate the changes that are constantly unfolding themselves before his vision. The more diversified these changes become, the greater is the difficulty of correct appraisal. It seems justifiable to remark that at no other time have changes in the social, economic, and scientific aspects of modern civilization progressed more rapidly than now. The practice of surgery shares equally in these changes. To many caught in the hurly burly of active life it is impossible, and probably seems unnecessary, to stop and scan the progress that is being made though it undoubtedly is wise to check up from time to time on the direction toward which general advances are being made and to emphasize the tendencies which seem to offer the greater progress.

Occasionally philosophical contributions to our surgical literature appear in which the author is courageous enough even to contemplate the future such as the delightful essay entitled *La Chirurgie de la Douleur* by René Lenche. Such a contribution must have for its inception a complete understanding of the actual state of practice in our time and represents a thoughtful attitude that in the long run is sure to exert a beneficial influence upon our field of work.

Recently driven by an interest in the surgical literature of that great epoch between the advent of anesthesia and the discovery of bacteriology I found myself plunged into that era of surgery in which great speed in operating was a dominant characteristic. This led to what I have chosen to call "ablation" surgery. Great portions of the body were removed rapidly with the knife in order to get rid of a small diseased part. This speed

was partly a legacy from the time when anesthesia was unknown and when speed in operating therefore diminished suffering. But it was also dictated by the fear of what might happen were the patient kept too long asleep, a fear engendered by the spectre of "ether pneumonia" (1). Lastly the speed represented the lack of a philosophical attitude toward the advent of anesthesia without doubt one of the greatest gifts our profession has ever made toward the comfort of man.

One of the chief tendencies in our modern development is the abolition of this attitude toward surgery. The enormous experience with modern anesthetics has given us great confidence in their safety and in particular the amount and duration of the anesthesia has been shown to play but a minor rôle in postoperative complications. Speed, once a necessity and therefore fashionable and popular, has been shown to be not only a non-essential but a positive menace. Surgery now rid of the specter of speed as a necessity has learned in this country largely through the influence of Halsted and his pupils a new, meticulous and gentle technique which considers every cell as valuable unless diseased.

To be sure amputations are still necessary, but they are performed in modern clinics only after every effort has been made to save the limb as a whole. This change of attitude toward the removal of major parts of the body is emphasized in the very critical studies relating to the possibility of restoring to a limb in which there is a damaged circulation sufficient blood supply to maintain the limb in a useful condition. The whole matter of sympathectomy in relation to impeded vascular channels and the great development of methods for testing the circulation of a limb and its possible restoration is an example of this. Technical improvements not only have permitted us this philosophical change toward

disease in surgical conditions but have enabled us to attack conditions heretofore too dangerous for operative intervention. Thus, the introduction of electrosurgery has enabled surgeons to attempt the removal of tumors such as those in the brain heretofore forbidden them. Whether the removal of such diseased parts is worth the price in suffering and economic loss, and result studies of survivals alone will tell.

This tendency for the preservation of all structures not actually diseased is constantly brought before us in the ever increasing and intelligent use of radiation in relation to tumors. Experienced surgeons fully appreciate the futility of surgical procedures in relation to certain very malignant tumors. Increasing diagnostic ability in which the X ray has proved of great assistance, has led to the early recognition of distant metastases, thus helping the surgeon to withhold a mutilating and useless procedure. Moreover we are now learning the great possibilities of radiation as a means of therapy in the treatment of neoplasms. So much have we learned of this that it may be said the day is almost at hand when the scalpel will not be considered in the treatment of certain of the more malignant sarcomata and embryonic forms of neoplastic growth.

Still more recently it has been shown that the eradication of certain congenital sinuses and fistulous tracts by a caustic solution may be a better method than the excision of these tracts with the scalpel. None of the methods are really new since the use of caustics and the cautery were methods practiced by Hippocrates and held equal position with the scalpel in the field of surgical therapy.

It appears that surgery today is characterized by a very sincere appreciation on the part of surgeons that every bit of tissue possible should be saved and particularly that structures taking part in important functions must be preserved. To this end we find introduced a great variety of new technical methods which seem increasingly to represent the one thing that has characterized the practice of medicine and surgery from a distant past, that is, to give to each individual patient the maximum benefit which can be given. It is perhaps surprising though surely worthy of our great tradition that in a day when scientific attitudes hold such a distinguished position in both the professional and public eye the profession of medicine in spite of its tremendous interest in the progress of science and its understanding of disease can still treat the patient rather than the disease.

ELLIOTT C. CUTLER.

EARLY AMERICAN MEDICAL SCHOOLS

THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO

CHARLES DAVISON A.M., M.D., F.A.C.S. CHICAGO

Professor of Surgery Emeritus University of Illinois

THE College of Physicians and Surgeons of Chicago was incorporated October 14, 1881.

It was located at the corner of Harrison and Honore Streets, directly opposite the entrance to Cook County Hospital.

The College of Physicians and Surgeons was founded at a time when medical schools were largely proprietary institutions, owned and conducted by medical men. The founders were a group of young, active, pushing, ambitious medical men, experienced as junior members of the faculties of the existing medical colleges of Chicago. They sensed the timely opportunity for the entrance into Chicago of a new medical college. They appreciated the pedagogical value of graded courses of instruction. They recognized the proximity to Cook County Hospital as a great clinical teaching opportunity. They foresaw prestige and professional advancement for the members of the faculty of a new successful institution. They hoped for a profitable enterprise.

The original capital stock of the corporation was thirty thousand dollars, which was subscribed equally by the incorporators. Upon organization of the original faculty, the capital stock was increased to sixty thousand dollars, each additional member of the faculty being allotted stock to the amount of two thousand dollars.

The founders of the College of Physicians and Surgeons were A. Reeves Jackson, president, professor of surgical diseases of women and clinical gynecology, Samuel A. McWilliams, vice president, professor of clinical medicine, diseases of the chest and physical diagnosis, Daniel A. E. Steele, secretary, professor of orthopedic surgery, Leonard St. John, treasurer, professor of demonstrations of surgery, surgical appliances and minor surgery, and Charles Warrington Earle, professor of obstetrics. During the organization period there were added to the faculty, among others such well known men as Robert L. Rea, professor of principles and practice of surgery and clinical surgery, Frank E. Waxham, professor

of diseases of children, Henry Palmer, professor of operative surgery, clinical surgery and surgical pathology, John E. Harper, professor of ophthalmology, Oscar A. King, professor of diseases of the mind and nervous system, Henry Parker Newman, lecturer on obstetrics, Boerne Bettman, lecturer on ophthalmology and otology, G. Frank Lydston, lecturer on genito-urinary diseases.

The formal opening of the new institution occurred September 26, 1882, with 100 matriculated students present. The number of students in attendance gradually increased to 165, of which 52 graduated at the end of the session.

The clinical instruction to this class of students was given in the college amphitheater, the West Side Dispensary in the college building, the Illinois Charitable Eye and Ear Infirmary, and Cook County Hospital.

During the period of organization it was planned to present the entire subject of medicine in three annual pedagogically graded courses. The first year was planned to cover the fundamental subjects of anatomy, physiology, histology, chemistry, materia medica, therapeutics, and individual laboratory work; the second year to cover the principles of medicine, surgery, obstetrics, and the specialties; and the third year the practice of medicine, surgery, obstetrics, and their specialties, especially stressing a practical clinical training.

William E. Quine was appointed professor of medicine at the beginning of the second year, and thereafter the affairs of the institution were marked by his earnest, forceful, dominant personality. Nicholas Senn was appointed professor of surgery in 1882 and continued for 6 years with the institution. Christian Fenger, the great clinical pathologist and surgeon, was appointed professor of surgery at the beginning of the third year and occupied that chair for 9 years.

During the first 10 years the trials and difficulties of the college as a private institution were great. The administration of the institution was attended by ceaseless turmoil. There were fre-

quent changes in the faculty accompanied by great dissatisfaction, largely due to the policy which limited the faculty positions to those who owned the stock originally covering that particular subject. Charles Warrington Earle, who was one of the most stormy most persistent, and most capable of the objectors to the policies of the administration, was ousted. The college was not self supporting. The deficit at the end of 10 years was thirty thousand dollars.

At this crisis, in 1892 Dr Quine with the collaboration of Drs. Steele and Jackson, managed a reorganization. Charles Warrington Earle was made vice-president and professor of obstetrics, and Dr Quine president of the faculty. During this period there were notable additions to the faculty. John B. Murphy in clinical surgery, Henry T. Byford in gynecology, William A. Pusey in dermatology, Walter S. Christopher in pediatrics, Ludvig Hektoen and later William A. Evans in pathology.

A laboratory building with complete accommodations for the departments of anatomy histology embryology biology chemistry and pathology was erected and occupied in 1893.

The Quine Library, founded at this time became the depository of many medical books presented by Dr Quine and other members of the faculty and their friends.

The West Side Hospital was organized in 1896 by medical practitioners interested in the college, and soon became a center of college clinical activity.

These were years of material prosperity for the college there were more than 300 students in attendance in 1896. William A. Pusey was secretary. His vigorous activities added greatly to the prestige of the institution.

A new era in medical education was developing. The day of private medical schools was passing. The university plan of medical education was in evidence. The American Medical Association was demanding preliminary university training as an essential prerequisite. There was a general effort being made throughout the country to bring the well established independent medical schools into organic relationship with the universities. The Chicago Medical College, one of the earliest and best medical institutions in Chicago had been incorporated in Northwestern University as its medical department. Rush Medical College had affiliated with the University of Chicago.

Under these circumstances it was very reasonable that the University of Illinois should desire an affiliation with the strongest independent

medical institution in the state. It was very reasonable that the College of Physicians and Surgeons would welcome the prestige of a connection with the state university.

Acting upon a suggestion of Governor Altgeld to Dr Quine and to the board of trustees of the university an affiliation agreement between these institutions was signed April 1 1897. By its terms the College of Physicians and Surgeons was leased to the University of Illinois as its medical department for the period of 4 years. The medical college was conducted by the same individuals as officers and faculty but under the technical supervision of the University of Illinois. The university assumed no financial responsibility.

The results of this experiment were so satisfactory that an extension agreement was made for 25 years, beginning May 1 1900, at the termination of which ownership of the College and all of its property was to be vested in the university. During this period one-third of the net profits was to go to the university and two-thirds to the stockholders of the college corporation. The institution was designated as the "College of Physicians and Surgeons, College of Medicine of the University of Illinois." This arrangement was followed by an era of prosperity with a rapid increase in student attendance, reaching at one time a registration of 720.

Accommodations in the original building having become inadequate by agreement with the trustees of the university the adjoining public school property was purchased in 1900 by the college corporation and converted into a medical college building, thus greatly increasing the debt of the corporation.

The University Hospital was built and equipped by a small group of the faculty to provide more stable clinical teaching facilities.

The more rigorous requirements in medical education, the insistent demands for more adequate equipment and more elaborate methods of teaching increased the cost of administration. The requirements of higher standards of admission diminished the number of students and therefore the income. The financial condition of the college became almost untenable. To avoid the criticism that any appropriation by the legislature might directly or indirectly aid a private corporation, the 25 year partnership agreement was abrogated and a direct lease to the university of the college property for eighteen thousand, five hundred dollars a year was substituted.

Efforts by the university to obtain financial aid for the medical department from the legisla-

The College of Physicians and Surgeons of Chicago

ture failed on several occasions because of legislative technicalities and antagonistic litigation. No part of the general appropriation of the university could be used legally for the support of the medical school, the income of the medical school was derived entirely from student fees. The trustees had never expended a single dollar of money appropriated by the state to the university upon the medical department.

The existing conditions were so unsatisfactory to the directors of the College of Physicians and Surgeons that they decided to continue no longer the lease of their property to the university. Accordingly, President James discontinued the medical department of the university on April 30, 1912.

The announcement by Dean Quine that the medical school would no longer be leased to the University of Illinois and that the College of Physicians and Surgeons of Chicago would reopen its medical school caused great consternation among the faculty, students, and medical alumni. An active and influential group of the faculty refused to take part in the reorganization of the College of Physicians and Surgeons as a teaching body. These men hoped for the continuance of a medical school in Chicago under control of the University of Illinois. The annual election of the medical alumni resulted in an overwhelming victory in the interests of the university.

About this time it was suggested by President James that if it were possible for the medical alumni to gather up the stock of the corporation of the College of Physicians and Surgeons and present it outright to the University of Illinois together with the absolute ownership and control of the property it would be the best solution of the difficult problem. It would save to the university the fruits of its previous work in medical education, it would prevent the rivalry incident to another medical college being introduced into the field. It would bring back into the fold the friends of the College of Physicians and Surgeons, and it would furnish a plant already in existence under the absolute control of the university in which to conduct its medical work.

The alumni association recognized that to obtain all of this stock by donation or purchase in a limited time would require an unanimity of effort between the alumni, active friends of the university, and influential representatives of the College of Physicians and Surgeons. With this in view, a committee was appointed by the alumni association to take charge of the efforts to secure the stock for the university. This committee consisted of Edward Louis Heintz, president of the Medical Alumni Association, D. A. K. Steele, president of the College of Physicians and Surgeons, and the writer, an ex trustee of the University of Illinois.

After an intense campaign by this committee, possession of the entire issue of stock of the College of Physicians and Surgeons was secured by donation, subscription and purchase, for a gift to the university. The complete stock issue of 2 170 shares of the Corporation of the College of Physicians and Surgeons of Chicago deeds to its real estate subject to certain encumbrances, a bill of sale of its personal property, its scholarship investments, its balance in bank (\$12 551.11) and the resignations of the officers of the corporation were delivered to the president of the board of trustees by this committee as a gift to

the University of Illinois from the Medical Alumni Association of the University of Illinois.

The board of trustees formally accepted the gift on behalf of the University of Illinois on February 13 1913, and directed the president of the university to reopen immediately the medical department.

The College of Physicians and Surgeons of Chicago passed out of existence when this transfer was completed. It has become a memory—a pleasant memory to some of the older members of its faculty increasingly pleasant with the reverse of the years.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

CHRISTOPHER'S *Minor Surgery*¹ now in its second edition promises to become one of the standard American textbooks on the subject. The thoroughness with which Dr Christopher has covered the literature is evidenced on every page and it is a pleasure to see that procedures and ideas emanating from other sources are duly credited, even though the author may not at times agree. Although numerous methods of treatment are frequently outlined for a single condition, Christopher indicates his choice and the logic upon which the choice has been made.

The book is profusely illustrated with numerous line drawings and photographs of diseased conditions and procedures. It would be very difficult to duplicate these illustrations without consulting many textbooks. The value of the book to the young practitioner and the interne is considerable since in it are described all of the minor surgical procedures and technical procedures which they are called upon to perform. Since the book is restricted to minor surgery it deals often with subjects which are but cursorily treated in textbooks of surgery. Genito-urinary, orthopedic, gynecologic, and rectal conditions so long as they belong properly to the realm of minor surgery are fully described thus making reference to special textbooks unnecessary. A broad conception of surgery such as Christopher has shown is both welcome and refreshing.

MICHAEL L. MASON

THE outstanding contributions to large bowel surgery by the Mayos, Judd and Rankin are epitomized in Rankin's recent book.² It will, therefore, be widely read and constitutes a valuable reference book on this subject. Emphasis is placed on the importance of malignancy contributing two-thirds of the major lesions of the large bowel and rectum. Accepted methods of diagnosis and treatment are considered. In particular consideration is given to the roentgenoscopic examination of the large bowel which now permits accurate localization and recognition of the pathologic type in more than 95 per cent of lesions of the large bowel. Statistical data dealing with operability, operative mortality and longevity following surgical procedures

in malignancy, offer encouragement to patients so afflicted and reflect the advances made in the surgical management of these diseases.

The chapters on anatomy, physiology, and congenital malformation of the rectum are excellent both from the standpoint of text and illustrations.

The chapter on diverticulosis and diverticulitis is based on the study of a large number of patients and summarizes the many contributions to the subject of the Mayo group. The drawings illustrating the early beginnings of diverticula of the colon substantiate the Beer theory of origin, namely, that herniations of mucosa occur through weakened or fragmented circular muscle fibers of the large bowel.

In the treatment of megacolon the classical contributions of Judd and Adson and Rankin and Learmonth on lumbar sympathetic ganglionectomy are given careful description and illustration.

A detailed account is given of the bacteriological causes and experimental production of ulcerative colitis based on Bergen's work. While many workers in this field may not agree with the importance of the diplo-streptococci as a causative factor the evidence is fairly presented and therefore must stand the test of time and further study. The description and illustrations of the proctoscopic examination of the bowel with the varying changes in the mucosa in different stages of the disease are of great importance to the diagnostician. The entire chapter is one to be highly recommended to all those who have suffered with their patients in the treatment of this disease.

The chapter of polyposis considers thoroughly the pathology and tendency to malignant degeneration of polyps which stud the whole colon from the caecum to the anus, in the condition known as multiple polyposis. To the casual reader it may not be apparent that the pedunculated adenomata described under the heading of benign and rare tumors are by far the most common type of mucosal polyps found in the rectum and colon. These are often present in young childhood, and in the opinion of the reviewer are by gross and microscopic examination and course nearly always benign.

The material presented on cancer of the colon and rectum is splendid. It reflects the outstanding work in this field at the Mayo Clinic and presents a chapter of exceeding interest to all who are concerned in the surgery of cancer. If for no other reason these chapters fully justify the book. One of the outstanding contributions to colon surgery is Rankin's modification of the Mikulicz operation which he calls obstructive resection. A review of the rather dis-

¹MINOR SURGERY. By Frederick Christopher, F.R.C.S., M.D., F.A.C.S. With a foreword by Allen B. Kohn, M.D., F.A.C.S. 3rd ed. Philadelphia and London: W. B. Saunders Company, 1935.

²THE COLON, RECTUM, AND ANUS. By Fred W. Rankin, B.A., M.A., M.D., F.A.C.S., J. Arnold Bergen, B.S., M.D., M.S. (Med.), F.A.C.P., Louis A. Eide, B.A., M.D., F.A.C.S. Philadelphia and London: W. B. Saunders Co., 1935.

encouraging results of cancer of the rectum by radium treatment is given by Bowing.

In discussing the causes of rectal stricture the authors properly throw doubt on the importance of tertiary syphilis as a causative factor. Lymphogranuloma inguinale and its identifying Frei test is not mentioned as a possible cause of rectal stricture, but it is of course true that this factor is not definitely established.

In the chapters given over to anal infections, pruritis ani, and hemorrhoids, there are numerous points where honest difference of opinion exists. For example, the author's statement that "the supposed incomplete external fistula is an impossibility" lacks authority.

The concluding chapter on operative procedures is well done and includes, as do most chapters in the book, a good bibliography. VERNON DAVIS.

THE authors of *Treatment of Syphilis*¹ have endeavored to present this important subject in as condensed and simple form as is possible. In this they have succeeded well. There are thirty-three chapters, eleven of which are devoted to the various methods of administering mercury in syphilis, the pharmacology and chemotherapy of mercury and the histological changes induced by it, and mercurial reactions, and their treatment. Two large chapters are devoted to blamuth therapy.

There are twelve chapters in which the arsenobenzenes are discussed. This discussion includes the history of their development, their chemotherapy and toxicity and the methods of their distribution and excretion. Reactions and fatalities following their use are thoroughly treated, and the technique of their administration is described in detail.

Two chapters are taken up with a discussion of the iodides and other metals, and one chapter is given over to the prophylaxis of syphilis.

The book is a fairly large one, and the subject is covered most thoroughly. The text is replete with references to the current literature, both foreign and domestic. The bibliography is indexed in an orderly manner and is a complete one. There are 63 excellent illustrations.

For anyone interested in the subject of syphilis, whether he be general practitioner or specialist, this book should prove to be of inestimable value. It is an excellent treatise and a distinct contribution to the subject of syphilis. EDWARD A. OLIVER.

IN his monograph² Rydberg has presented a very complete study of cerebral injury in newborn children from both the clinical and the pathological anatomical aspects. He lays a logical foundation for his study in a review of the normal anatomy and

histology of the cerebral structures. This portion of the work receives wider treatment than the main subject would seem to warrant. The author from his investigations agrees with the present accepted theories regarding the origin and development of the glial structures except in the case of the ependymal microglia. His observations on human and animal fetal brains reveal all evidences to be in favor of the common ectodermal origin of the whole glia.

He discusses at length theories dealing with the pathogenesis of intracranial bleedings in the newborn, and records theoretical and experimental observations as to the influence of the birth process upon the blood circulation in the fetus.

The author also records the anatomical observations on a series of autopsies upon 100 consecutive newborn fetuses dying during parturition or within 10 days thereafter. He made a very complete gross and microscopic study of these specimens and has correlated them carefully with the clinical manifestations. The symptomatology and diagnosis of birth trauma brain injuries is thoroughly covered and chapters are devoted to prognosis and treatment of these conditions.

The case records of 50 cases observed by the author form an appendix of value to the obstetrician, the pediatrician, and the neurologist. The work is complete with a large and inclusive bibliography. HAIR HAYES.

THE new *Textbook of Pathology*³ by Boyd is admittedly not intended for practitioners of medicine or of pathology but for students of pathology only. The practitioner says Dr. Boyd in his preface, needs a book of reference. The student, on the other hand, needs a book from which he can gain a grasp of the fundamental principles underlying the subject. His time is too limited to permit its dissipation in "intriguing rarties or the newest notion of the moment." With this audience and these ideas in view Dr. Boyd has produced a textbook of pathology which is smaller by almost a hundred pages of text than any of the three best known textbooks on this subject now in use in America. The preface is not the least interesting part of the volume inasmuch as it gives a clear statement concerning the changed outlook of pathology and its relation to other branches of medical science.

In accordance with the usual custom in books on this subject this volume is divided into two parts. Part I deals with general pathology, which is the elucidation of the vital processes which underlie the end-results studied by the morbid anatomist. The study of disease from the physiological point of view. The book opens with a chapter on inflammation, which "forms the best starting point for the study of pathology as a whole." Without making inflammation a purposive reaction, the discussion emphasizes the functional side of all phases of the

¹TREATMENT OF SYPHILIS. By Jay F. Schindler, A.B., M.D. and Carroll R. Wright, B.S., M.D. New York and London: D. Appleton and Company, 1921.

²CEREBRAL INJURY IN NEW-BORN CHILDREN: CONSEQUENCE OF BIRTH TRAUMA WITH AN INQUIRY INTO THE NORMAL AND PATHOLOGICAL ANATOMY OF THE NEUROBLAST. By Erik Rydberg. Copenhagen: Levin & Munksgaard, 1921.

³A TEXTBOOK OF PATHOLOGY: AN INTRODUCTION TO THE STUDY OF DISEASE. By William Boyd, M.D., M.R.C.P. (Ed.), F.R.C.P. (Lond.), Dpt. Path., F.R.C.P. Philadelphia: Lea and Febiger, 1921.

process. The chapters on infection and immunity, degenerative processes, circulatory disturbances, animal parasites, infectious granulomata present clearly the important established facts concerning these subjects. The chapter on tumors is limited to 54 pages and is perhaps too brief, especially the discussion of some types of tumors, to give the student an adequate comprehension of the subject.

Part II, special pathology, begins with a discussion of the pathology of the heart and blood vessels and proceeds through the various organs and systems of organs. The section on nephritis is especially to be commended for both its brevity and its comprehensiveness. A helpful discussion of the newer established facts concerning the physiology of the female generative organs of bone and of the glands of internal secretion opens the chapters dealing with the pathology of these organs. Throughout the volume paragraphs on relation of symptoms to lesions should stimulate in the student an interest in the subject.

The literary style of the author is clear, concise, stimulating and interspersed with numerous striking bits of description and allusions that make the reading of this volume a pleasure. He speaks of cells "trapped in the pathless forest of the pulp" of the spleen. In connection with syphilis of bone he refers to the "nocturnal boring pains alluded to by the Psalmist." The incidental historical reference to the discovery of tar cancer on page 220 is especially interesting and should give to students a correct viewpoint toward research. The otherwise delightful literary style is marred by only one fault, namely the use of too many short sentences.

The volume can be commended for its clearness, its conciseness, and its readability. It will, on most subjects, meet adequately the needs of medical students. It may also be read with profit by practitioners of medicine and surgery who desire to indulge in the periodic brain-dusting recommended by Osler¹ and to acquaint themselves with the modern point of view of pathology which is no longer "an outworn creed, a science as dead as the material with which it deals." Pathology in relation to the living patient is the motif of this book. The subtitle, "An Introduction to Medicine, is therefore justified.

J. P. SIMONSON.

IN a 325 page monograph¹ Grollman discusses the subject of the amount of blood pumped by the heart in unit time. Dr. Grollman is associate professor of physiology in the Medical School of Johns Hopkins University and has devoted a number of years to this type of study. The book contains a critical review of the various methods formerly in use and a detailed account of the acetylene method.

The physiological variations of the cardiac type as studied by this method include the effects of posture, ingestion of food and fluids, sleep, menstrua-

tion, emotion, temperament, exercise and altitude. Another series of studies were made of the changes of cardiac output considering the effects of alcohol, caffeine, tobacco, carbon-dioxide, adrenalin and the vaso-depressants. The cardiac output was studied in various types of cardiovascular diseases and abnormal cardiac physiology.

The bibliography is complete and the book is well indexed. The printing and binding are excellent. It will be of particular interest to those who are active in research in cardiovascular physiology in the clinic or in the laboratory. CHAUNCEY C. MANER.

ENDOCRINE medicine is discussed by Engelbach² in a 3 volume work of over 1800 pages profusely illustrated. The first volume on general considerations covers the research history, anatomical development, physiology of the endocrine glands, the etiology of their diseases, diagnostic procedure and the relation of endocrine disorders to public health. The second and third volumes are composed of four main sections in which endocrine diseases of infancy, juvenility, adolescence and maturity are discussed. The emphasis throughout the work therefore is on the life-long character of the endocrinopathies and on their appearance in all age periods. This point of view is in some part due to the demonstration of the growth hormone. Abnormality of this function of the anterior pituitary must be determined by comparison with a normal curve of growth. A valuable feature of this work is the inclusion of tables of measurements and x-ray studies of bones from infancy to maturity. The prominence given the infantile and juvenile endocrinopathies is justified by statistical analysis of the 3000 cases which make up the clinical basis of the book. Of the diseases occurring in this series 40 per cent were believed to have started in infancy or childhood. It is axiomatic in general medicine that prevention is the best treatment, obviously in this group of diseases prevention of adult disorder begins during embryonic life, hence the endocrine status of the mother must be analyzed and corrected. To follow out the same line of thought, a section on senility should be added.

The adult endocrinopathies covered in section five are thyroid disorders, hypophyseal disorders, composed of anterior lobe pituitarisms, adiposogenital pituitarism, pituitary tumors, and neuro-pituitary disorders, bi-glandular disorders of the thyroid and pituitary, gonadal disease, and thymic syndromata. Parathyroid conditions, covered originally as they appear in infancy and childhood, are again described in a single chapter relating to adolescence and maturity. In this discussion tetany and hyperparathyroidism are presented.

¹Endocrine Monograph, by William Engelbach, M.D., F.A.C.P., B.S., M.S., D.Sc. With a foreword by Llewellyn F. Butler. Vol. I.—General Considerations, Vol. II.—The Infantile Endocrinopathies, The Juvenile Endocrinopathies, Vol. III.—The Adolescent Endocrinopathies. The Adult Endocrinopathies. Springfield, Illinois, and Baltimore, Maryland: Charles C. Thomas, 1932.

²THE CARDIAC OUTPUT OF MAN IN HEALTH AND DISEASE. By Arthur Grollman, Ph.D., M.D. Springfield, Illinois, and Baltimore, Maryland: Charles C. Thomas, 1932.

Throughout all sections case histories are used, charts given, X-rays and histological sections reproduced, and therapeutic experience quoted. The hormone preparations now available are evaluated and indications for their use given.

The complete picture of endocrine physiology and disease in man will not be presented for many years. At the present time this work describes well known endocrine entities in the light of the latest discoveries but, in addition, will have a permanent place in medical literature because of its teaching of the endocrinopathies as life-long processes beginning in infancy and continuing on through childhood, adolescence, and maturity.

A fourth volume is being prepared for the diseases of the pancreas, suprarenals, and liver.

PAUL STARR.

AZEMA presents a comprehensive monograph¹ on spondylolisthesis. After a short historical review he enters into an extensive discussion of the lumbosacral anatomy and the mechanics resulting in the anterior displacement of the vertebral body. The influence of the upright position in the production of spondylolisthesis is emphasized. Attention is called to the loss of bony continuity at the isthmus (pars interarticularis) of the lamina and the loss of rigid support at the base of the vertebral column. After a very thorough portrayal of the clinical manifestations of this condition, the author describes the methods of treatment and adds a surgical procedure of his own. This monograph is well illustrated with many diagrams, photographs, and roentgenograms. An excellent résumé of the subject of spondylolisthesis to the present date.

FREDMONT A. CHANDLER.

A DISTINCT need in experimental pathology has been filled in the small volume¹ by Hagoner and Coates. The frontispiece is a portrait of Julius Friederich Cohnheim, the most eminent of Virchow's pupils, who by brilliant experiments on living animals revived a pedantic subject and demonstrated to others a method of investigation which, in a few brief years, has yielded incalculable benefits to mankind. The book is divided into three sections. The first deals with surgical technique and experimental methods, anaesthetization of the experimental animals, general care of the experimental animal, and normal blood findings in laboratory animals. The general principles of surgical technique are briefly but adequately described, and the different types of knots and sutures are well illustrated. The necessity of care in anaesthetization is strongly emphasized. In the foreword Professor Krumbhaar remarks, except for the appalling ignorance in some non-medical circles of the conditions under which animal experimentation is carried

in Germany. By Max Azema, M.D., F.R.C.S., and Company 1932.

A HANDBOOK OF EXPERIMENTAL PATHOLOGY. By George Wigglesworth, M.D., and R. Philip Coates, M.D. With a foreword by Edward Paul Krumbhaar. Springfield, Illinois: Charles C. Thomas.

on, it would be unnecessary to mention that absolute asepsis, general anaesthesia, and similar precautions are carried out wherever indicated, with as strict conscientiousness as in the human operating clinic. In fact, such conditions are usually essential to the success of the experiment as well as obligatory from humane points of view. The second and third sections are concerned with methods of producing general pathological conditions and lesions of special organs. One hundred and nineteen experiments are described clearly and in such adequate detail that they can be carried out by any intelligent student. Most of the procedures for inducing pathological conditions have been well selected. Many of the more complicated methods, such as Mann's technique for inducing gastric ulcer by various types of gastric and intestinal anastomoses, have been omitted. The typography is excellent. Large, clear type and heavy unglazed paper render reading easy. The binding in heavy brown Holliston book duck is admirable for rough use in a laboratory. Following the descriptions of many experiments one or more references are given to important papers which will aid the student in technique and, especially, in interpreting his results. As there is no book of similar scope in English, this volume will be welcomed by teachers who wish to introduce their students to the field of experimental pathology either as a special elective course or as an accessory to the routine teaching of general and special pathology. J. P. SIMONE.

THE book¹ by Crile and his associates is not a formal treatise on the thyroid gland but as its preface states, is an account of the experience of the staff of the Cleveland Clinic in the treatment of diseases of that organ. In a sense then it is a binding together of many small articles—some profound, others very superficial. Dr. George Crile, Jr., writes the chapter on iodine and the thyroid gland. Dr. D. Roy McCullagh a short summary of the biochemistry of iodine. Dr. Crile writes on the rôle of the thyroid gland in the energy system, on endemic goiter, and on the mechanism of hyper- and hypothyroidism. Dr. Charles L. Hartsock discusses clinical aspects of hypothyroidism. Drs. Tucker and McDonald briefly describe the diagnosis of hyperthyroidism. Dr. E. Perry McCullagh writes a valuable chapter on the differential diagnosis of hyperthyroidism. Dr. Robert S. Dinamore writes briefly on hyperthyroidism in children. No careful analysis of the physiologic results in this interesting field is given. Dr. John P. Anderson writes briefly on cardiac disturbances associated with hyperthyroidism. Two good articles are those by Dr. A. D. Roederman on ocular changes in hyperthyroidism, and by Henry J. John on carbohydrate metabolism in hyperthyroidism. A valuable treatise on roentgenological observations in thyroid disease by Dr. Bernard H. Nichols, well illustrated with X-ray films, serves to

DIAGNOSIS AND TREATMENT OF DISEASES OF THE THYROID GLAND. By George Crile and Associates. Philadelphia and London: W. B. Saunders Company 1932.

emphasize the importance of substernal goiter. Malignant and inflammatory conditions of the thyroid are discussed in a series of chapters. Operative technique is described and illustrated by Dr. Dinmore. Special considerations in the technique are discussed in a separate chapter by Dr. Crile. The diagnosis and treatment of parathyroid tetany is covered in a good chapter by Dr. E. Perry McCullagh. The book concludes with a short chapter on end results of operations for hyperthyroidism by Dr. George Crile.

On the whole the book is, of course, interesting and a variety of illuminating studies from unusual angles are gathered together here. In general, however, one would conclude that most of these studies are too brief and too superficial to be of much value. The book is of interest to the student of thyroid diseases but not the authoritative treatise with which one would begin the study of those disorders.

PAUL STARR.

A BRIEF review of the most important advances in obstetrics and gynecology published in the past few years is contained in the third edition of the book¹ of Bourne and Williams. The book is written in a simple and direct manner as a coherent text and not merely as a collection of abstracts. New material has been added on the subjects of anaesthetics in labor, carcinoma of the cervix, and functional uterine hemorrhage. There is also a chapter on the X-ray in obstetrics and gynecology which is illustrated with excellent prints. The book bears evidence of thorough revision of previous editions and will prove valuable to the physician who wishes to keep abreast with the growing literature.

LESTER F. STEIN

THE work² of Wuerdemann now in its second edition is still the only book in English since that of Ramsay in 1907 devoted to the subject of injuries of the eye. The text has not been materially lengthened and the number of illustrations has been reduced by more than one hundred. Those which are retained are of good quality, however, and are for the most part original. The paper and type of the present edition are excellent, a great improvement in these respects over the first edition.

The author shows his familiarity with the German and French literature and acknowledges his debt to

RECENT ADVANCES IN OPHTHALMOLOGY AND OPHTHALMOLOGY. By Aleck W. Bourne, M.A., M.B., B.Ch. (Camb.), F.R.C.S. (Eng.), F.C.O.G., and Leslie W. Williams, M.D., M.S. (Londn.), F.R.C.S. (Eng.), M.T.O. 3d ed. Philadelphia: F. B. Rothman & Son, 1934. 125s.

²INJURIES OF THE EYE: DIAGNOSIS AND TREATMENT, FOREIGN PROCESSES AND VISION. By Harry Wuerdemann, M.D. 2d ed. F.A.C.S. 3d ed. St. Louis: The C. V. Mosby Company, 1933.

the large work of Wagenmann. He has also drawn from a large personal experience and many of the conditions described are illustrated by case histories, giving treatment and results. In removing foreign bodies from the eye by the electro-magnet the author prefers the anterior route, as a rule, by which the body is drawn around the lens into the anterior chamber, whence it is removed by corneal incision. The importance of X-rays in every case of suspected or even possible foreign body is emphasized.

Eighty pages are devoted to medicolegal questions, including important legal decisions and an abstract of the Workmen's Compensation Laws of the various states as they affect ocular injuries. Under these laws, compensation for loss of both eyes (total disability) varies from one thousand dollars (Georgia) to fifteen thousand dollars (South Dakota) averaging six thousand dollars. That for loss of one eye varies from six hundred dollars to two thousand eight hundred and eighty dollars, averaging about two thousand dollars.

One misses from this book a consideration of some important recent work. Nothing is said about injuries with tear gas, especially as to the use of sodium sulphite in glycerine as a solvent which was described by McNally. In considering enucleation of the globe and its substitutes, no mention is made of simple evulsion with retention of the cornea, an exceedingly valuable procedure. The operation described by the author is the old one with removal of the cornea, to which his disparaging remarks may well apply.

SAMUEL R. GIFFORD

THE monograph³ on acromegaly by Atkinson is one of those concise but exhaustive collections dealing with a particular disease that no one interested in the subject can afford to be without. It is a straightforward presentation of all the reported findings, gathered from an exhaustive analysis of the world's literature. It consists of two main parts—a series of chapters presenting the findings of different authors concerning the historical, clinical, pathological, diagnostic, and therapeutic aspects of the disease, and a series of analytical tables covering the results of removal of the pituitary gland, the post-mortem findings, the eye findings, a tabulation of certain features of the 1,319 cases that the author has collected from the literature and finally a bibliography covering 63 pages. I am impressed with the thoroughness and clearness with which this review is presented.

skin glands which are classified morphologically as acinous and tubular glands. Functionally they are divided into sebaceous and sweat glands. The breast is a modified sweat gland.

In an early stage of the embryo the ventrolateral surfaces of the body show a broad linear band of high epithelium generally known as Schwalbe's milk streak. The first anlage of the breast in humans appears in the last half of the second month of fetal life. Numerous puctuate epithelial thickenings are visible along the milk streak. They are known as milk points or mammary fields and consist of circumscribed epidermic proliferations in the shape of a tiny mound. These milk points are quite prominent in human embryos ranging from 28 to 60 millimeters in size. In so much as only one pair of breasts are ordinarily present in newborn and adult humans, the other anlagen are presumably those of supernumerary breasts because they are of similar histological make-up and correspond to the natural locations of aberrant breast tissue when it does occur. In the early stages of development, the mammary gland corresponds very closely to the origin and differentiation of sudoriparous glands. The sweat glands adjacent to the breast appear much later in the embryo but in significantly close relationship. The primitive breast differs from the early sweat glands only in the exceptional size of its tubules.

In the fifth month of fetal life, the lentil shaped plaques in the malpighian layer of the epidermis, which we have referred to as milk points begin to invaginate and dip down into the underlying connective tissue as solid cords which later acquire lumens. The milk point contains a basal layer of cylindrical cells with oval nuclei, the longitudinal axes of which are in a vertical plane. External to these cells are several rows of small polygonal cells with round nuclei. These solid cellular cord-like proliferations originate from the cylindrical cells in the superficial epidermic plaques. These proliferations become club shaped and extend farther downward into the connective tissue where they branch off into similar solid secondary buds. In the meantime, the connective tissue surrounding these

cords thickens and forms areolar tissue. At this stage in the development of the breast the tubules do not differ from the ducts of the meibomian glands, the early hair follicles or the sweat glands. The primary cords or tubules later develop hair follicles with corresponding sebaceous glands and the secondary buds divide into the ducts of the breast proper. These ducts extend deeply into fatty tissue which is arranged in embryonic fat islands. Toward the end of fetal life there is formed in many places, especially in the middle part of the tubule, a differentiation of the layers corresponding to those of the large sweat glands so that eventually the ducts contain two layers of cells an inner secretory layer and a basal layer such as in the adult gland. The blind tubules in the resting stage do not show the typical acinous structure until later life when they become functional.

Kolliker and Benda are both agreed that the breast is of sweat gland origin. The abundant histological evidence in the breast justifies this belief. Rudimentary sweat gland structures can be found in almost every breast, if diligent search be made. Some of the tubules of sweat gland origin developing beneath the areola of the breast empty into the mammary ducts rather than on the surface of the skin in a manner similar to the primitive hair follicles. The hair on the glandular field usually disappears in the progress of development together with the accompanying sebaceous glands. The sweat glands may or may not remain if they do they retain their ordinary relation to the lacteal ducts. This anatomical arrangement, as will be shown later accounts for the occasional occurrence of sweat gland adenomata and carcinomata immediately beneath the nipple.

There are at least five different interpretations of the significance and histogenesis of the so called sweat gland anomalies in the breast either normal sweat glands, sweat gland cysts, or sweat gland tumors.

a. Extramammary sweat glands of the skin are said to be included accidentally in the tissues of the mammary gland as aberrant cell rests (Creighton).

b. The sweat gland structures represent an arrest in the development of the breast in

Fig. 1. Development of breast. Human embryo 14 centimeters in length. The milk point or anlage of the breast, showing it to be a cutaneous merocrine gland. Note the basal columnar cells and superjacent polygonal cells with round nuclei in the rudimentary nipple. The early lacteal bud is morphologically indistinguishable from a primitive sweat gland tubule.

Fig. 2. Development of breast. Human embryo 14 centimeters in length. Another milk point showing several lacteal ducts which have acquired lumens. At this stage the resemblance to sweat gland tubules is obvious and significant.

these locations at a phylogenetically early stage which we may call the sweat gland phase i.e. incomplete mammary differentiation. Von Saar was first to correlate these structures with sweat glands; he believed that they indicate "a phylogenetic level at which the breast tissue had differentiated itself from sweat glands."

c. The sweat gland tubules, cysts and tumors in the breast are atavistic phenomena due to metaplastic changes in the lacteal ducts, which become dedifferentiated into an embryologically earlier cell type (Prym Dreyfuss).

d. True sweat glands are normally present in every breast where they anastomose with and empty their secretions into the interlobular lacteal ducts (Ewing).

e. The pale epithelial cells comprising these structures are said to be entirely unrelated to sweat glands. The morphological changes and peculiar staining affinities are attributed to degeneration of these cells in which they simulate but do not constitute sweat gland epithelium (Dawson).

It seems fundamentally unimportant to us to determine whether these peculiar mammary structures are anomalous embryonal, normal, or degenerative. The major premise has been that the breast is a modified sweat gland; the

appearance of apparent sweat gland tubules and cysts in the breast is a logical occurrence even though the mode of origin remains in dispute. It is significant to us that the anatomical and staining characteristics of these cells remain through all the transitional phases of normal sweat gland tubules, cysts, intracystic papillomata, adenomata, and car-

Fig. 3. Development of breast. Human embryo 33 centimeters in length. Intermediate differentiation of the breast. Serial section to show the early anastomosis of sebaceous glands with lacteal buds. These sebaceous glands and the numerous hair follicles seen at this stage are transitory and are not found in this close relationship in the fetus at term. At the base (arrow) a lacteal duct with two cells layers can be seen. It is of typical sweat gland structure.

Fig. 3. Cystic sweat gland tubules in a normal breast. The adjacent lacteal lobules stand out in marked contrast to the sweat gland tubules, because of the difference in size, structure, and staining qualities of the cells.

cinomata. This maintenance of cell type in the evolution of sweat gland tumors is a strong argument against the degenerative theory. Careful microscopical scrutiny of serial sections of these breasts frequently reveals the site of anastomosis of lacteal and sweat gland ducts. The abrupt transition in the character of epithelium lining these ducts is noteworthy if the process were degenerative it would probably not be confined so exactly to this duct system. Our studies have confirmed the theories of Ewing in regard to the histogenesis of these structures.

One is impressed in studying the structure of the developing mammary gland in the fetus, by the large size and abundance of sweat glands in the skin surrounding the breast. We believe it to be significant that the sweat glands of the newborn as compared with the adult are relatively enormously hypertrophied.

The development of the sweat glands in the skin corresponds in miniature to the development of the breast proper. The majority of sudoriparous glands originate on the finger tips, palms and soles in the fourth month of fetal life. Their anlagen resemble closely those of the breast. They project downward

as solid bulbous papillae the terminations of which become tortuous in the sixth lunar month. Intercellular clefts appear in the seventh month to form a continuous lumen in the tubule. At this time the distal end of the tubule becomes convoluted as in the adult sweat gland. In the axillary and inguinal sweat glands the tubules branch and form secondary buds as they do in the breast. The epithelium of the sweat gland duct acquires two distinct layers, an inner large celled secretory layer and an outer flattened myo-epithelial layer. The number of sweat glands in the skin are definitely determined at birth as are the number of hairs.

ANATOMY AND PHYSIOLOGY OF THE ADULT BREAST AND ITS RELATION TO SWEAT GLANDS

We have previously stated that sweat gland tubules are found in almost every breast. They seem to be more common in subjects with oily skin and considerable body hair and who are predisposed to acne and sebaceous cysts. The number of these sweat gland tubules in the breast is extremely variable. In some patients there are many and in others there are relatively few. Their locations in the breast correspond with the regional distribution of sweat gland cysts and sweat gland cancers in this organ namely in the axillary segment submammary fold and margins of the breast as well as immediately beneath the skin of the areola.

It appears evident that there are two types of ducts within the breast the lacteal ducts which form the bulk of the functioning glandular tissue and the occasional irregularly distributed sweat gland ducts. Hereafter in our discussion we shall employ the terms lacteal ducts and sweat gland ducts to distinguish these two structures. The investigator will find in serial sections of the breast that sweat gland ducts anastomose in the majority of cases, with the normal lacteal ducts. The mammary gland never presents typical entirely normal coiled sweat glands in its deeper structure. These sweat gland ducts represent various transitional stages from primitive sweat gland epithelium to normal lacteal epithelium. Such transitions may be observed in the ducts of the same breast.

Fig. 6 Two tiny cysts in a breast which is the seat of chronic cystic mastitis or Reclus disease. The cyst of the lacteal duct is lined by epithelial cells in two orderly layers, a basal germinating layer and an inner secretory layer. The cytoplasm of these cells is lilac colored and neutrophilic. The cyst in the adjacent sweat gland system in the breast illustrates the peculiar histologic features of hidradenoid cysts. The eosinophilia, the intracyclic papillary tufts, the plication or infolding of the epithelial lining, and the disposition of the club-shaped columnar cells are practically never found in cysts of lacteal ducts, but are commonly observed in apocrine sweat gland cysts of the axilla, groin, and scrotum.

The lacteal ducts of the mammary gland are lined either by a single, or more frequently a double row of columnar cells. They possess a relatively broad lumen. The membrana propria is supported by a connective tissue wall containing both longitudinal and circular elastic fibers but no muscle. The outer row is lower than the inner one. On the contrary there is only one epithelial cell layer in the alveoli, the structure of which differs during various functional states. Around the alveoli there may be found a small number of elongated stellate cells sending out long fine processes the so called basket cells the nature of which is in dispute.

The sweat gland ducts in the breast can easily be differentiated from the lacteal ducts by ordinary tissue staining. The inner secretory cell layer is not cuboidal or flat, but is composed of high columnar stratified epithelium with a tendency to papillary formation which is never seen in normal lacteal duct. These cells may be piled up on each other in the form of terraces. The staining peculiarities are quite striking. The cytoplasm contains fine granules which with even

Fig. 7 High power magnification of wall of sweat gland cyst in Figure 6. The cytoplasm of the club-like or luminal cells is granular and eosinophilic. The papillae vary in size and structure. They commonly have sparse stroma and occasionally they exhibit an arcade lowering or stratification of epithelium. The so called myo epithelial cells are not well shown in this section but in the deeper tissue there can be seen a thin encircling band of smooth muscle fibers. Muscle tissue is not found in connection with lacteal cysts or ducts except in the region of the ductal ampulla.

stain pink or even light red. This eosinophilia can best be appreciated in comparing sweat gland ducts and lacteal ducts in the same microscopical field. We are presenting a colored illustration showing this difference in the staining affinities of sweat gland epithelium and lacteal epithelium, in this picture the sweat gland duct is seen emptying into a lacteal duct (Fig. 4 frontispiece). At the site of anastomosis the transition between eosinophilic cells and neutrophilic cells is abrupt. Sweat glands in the normal skin have eosinophilic cytoplasm which characterizes the sweat gland ducts in the breast substantiates to some extent the homologous origin of these structures. Goldzieher and Kaldor on the other hand interpret this eosinophilia as a metabolic change in the lacteal cell which causes it to resemble sweat gland epithelium, they offer no evidence however to substantiate their opinion.

Another anatomical analogy which exists between the sweat glands of the skin and the sweat gland structures within the mammary gland is the frequent association of smooth muscle cells with the membrana propria of sweat glands of the skin and sweat gland structures in the breast. There are no muscle cells within the lacteal ducts but numerous

Fig. 9. Sweat gland adenoma in the skin overlying a carcinoma of the breast. The two tumors are adjacent but separate. The sweat gland tubules are enormously multiplied and cystic. This finding illustrates the consistent adherence to histogenic type in the benign and malignant sweat gland tumors of the breast (from Kroszpecher).

Fig. 10. Sweat gland adenoma in the skin overlying a carcinoma of the breast. The muscle fibers characteristic of sweat glands and their neoplasms are plainly visible (From Kroszpecher.)

ing the acini of these ducts are the so called basket cells, first described by Langhans in 1873. These spindle or stellate cells are found side by side in parallel arrangement and are bounded on the outside by the structureless stratum of the membrana propria and on the inner side by the epithelial layer. Their occurrence in the terminal vesicles is denied by Creighton and Benda and asserted by Nagel and Kuru. They are interpreted as smooth muscle cells by Kuru, Heidenhain and Benda. A definite fibrillation can be made out in these cells similar to that seen in other muscle cells; their staining reaction is also considered characteristic of the latter. As to their function it is believed to be that of contracting to express secretion from the ducts. In accordance with this view of their origin and character they have been designated as myo-epithelial cells. No cells of this character are visible surrounding the lacteal ducts proper but they are so frequently found surrounding the sweat gland ducts in the breast and are such an integral part of the sweat glands of the skin as to be considered characteristic of these structures. Kolliker in 1849 first

demonstrated the presence of smooth muscle cells arising from the outer epithelium of the sweat gland ducts in the skin. Kolosow in 1896 found persistent structures corresponding to these muscle cells in the breast proper. This muscle network is best shown in the sweat glands of the snouts in many animals.

There has been considerable argument as to whether or not these cells are actually smooth muscle cells. Some histologists have doubted this theory of their nature and have assumed that they are cells corresponding to ordinary mesenchyme, which somehow have become closely approximated to the ducts and alveoli. Such a conception has been expressed more recently by Dieckmann (1925). Others believe that these cells line capillary spaces running parallel to the wall of the ducts or cysts. Whatever their true character may be it seems significant that they are found fairly constantly in the sweat glands of the skin and are frequent in the sweat gland ducts of the breast. It was this analogy which prompted Benda to be the first to postulate the theory that the breast is a modified sweat gland. He found that the large sweat glands of the axilla and certain ducts in the mammary gland have in common an inner layer

Fig. 11. Wall of a sweat gland cyst in the breast. Immediately beneath the stratified epithelial cells are numerous fine muscle fibers, presumably of the myo-epithelial type. (From Krompecher)

of secreting epithelial cells and this outer layer of supposedly contractile muscle or myo-epithelial cells. The reason for the persistence of these peculiar cells in the sweat gland ducts of the breast and their absence in the lacteal ducts is that they represent a vestigial relic or survival of the earlier necessity for the contraction of ducts and expression of secretion which is not necessary in the human breast. Smooth muscle fibers are found within the nipple and within the adjacent portions of the areola of the normal breast. These are arranged in circular bundles at the base of the nipple the longitudinal fibers within its substance diverging into radiating bundles within the subcutaneous tissues of the areolar zone. Contraction of these fibers elevates and hardens the nipple, thus simulating the action of erectile tissues. In some way, this phenomenon is related to the action of the muscle fibers surrounding the sweat glands of the skin and aiding the excretion of sweat.

The sweat glands of the areola lie deeper than the sebaceous and Montgomery glands. They are found in the loose connective tissue between the base of the nipple and the glandular portion of the breast proper. This tissue is traversed by the true lacteal ducts 12 to 20 in number and it is around these vertical ducts that the small sweat glands are dis-

Fig. 12. Part of three sweat gland cysts of the breast. The "pale" columnar epithelial cells are shown in papillary and arcade formation. Radiating from the membrana propria of one of these cysts are many fine muscle fibers. (From Krompecher)

tributed. As we have previously stated, they may at times empty into these lacteal ducts rather than on the surface of the nipple. Creighton found them uniformly in six breasts which he examined. Krompecher and later Collin found sweat gland adenomata arising in this location and we have observed sweat gland carcinomata apparently arising from these structures.

In discussing the theory of sweat gland cancers of the breast and their relation to sweat glands of the breast we have been questioned about the distribution of sweat glands in the mammary skin. They are most abundant in the submammary fold and in the axillary segment and their function of secreting sweat is related somewhat to the menstrual cycle of the patient. In many women the breasts become moist when the rest of the skin is dry; this is particularly true at the onset of the menstrual period when the breasts enlarge, and the nipples readily become erect. In other words, the secretion of sweat on the breast and lactation by the breast are stimulated similarly by ovarian secretion. The activity of the sweat glands in the mammary skin was well

Fig. 13. Sweat gland carcinoma of skin of shoulder. Note the close histological resemblance to certain cellular or medullary varieties of mammary cancer.

Fig. 14. Sweat gland carcinoma of skin (not of breast). To show the infiltration of carcinoma cells among smooth muscle fibers which frequently surround sweat gland tubules.

shown by Sir Astley Cooper who studied the secretion of sweat in the skin of the breast after death. If the breast is wiped dry then compressed it will continue to perspire after being dried several times. This is observed more especially if the cuticle has been separated by putrefaction.

The mammary gland was formerly thought to be the homologue of sebaceous glands and the production of milk a process analogous to the activity of the latter. Gegenbauer even assumed a diphylectic origin of the breasts in different species. He believed that the breast in certain of the lower animals developed from primitive tubular glands of the sweat gland type whereas the breasts in other animals above the Monotremata in evolution have acinous lobular structure finding homology in the sebaceous glands. This theory is unsound and not substantiated by our studies. The secretion of the sebaceous glands entails a destruction or decomposition of the gland cell called by Virchow 'necrobiosis'. The lactating mammary glands never show stratification and subsequent destruction of the secretory cells which further disproves this theory. Kolliker and Virchow to the contrary. The manner in which the sweat gland secretes is not thoroughly known but there is sufficient evidence at hand to warrant the conclusion by anatomists and physiologists, that secretion occurs by the separation of soluble chemical substances from the cells.

The nuclei of the cells become pigmented and fat accumulates in the cytoplasm and is therein transformed into secretion. The process of secretion does not entail any destruction or even substantial changes in the sweat gland cell. Heldenbain found the breast to secrete in a similar manner except that it has differentiated to such an extent that it can secrete fat. Functionally both the sweat glands of the skin and the breast are merocrine glands in that they are secreting epithelial cells and do not undergo necrobiosis. The breast may therefore be defined as a modified sweat gland of the skin secreting milk, the unique component of this secretion being fat.

APOCRINE AND EXOCRINE SWEAT GLANDS—THE BREAST AS AN APOCRINE SWEAT GLAND

There are two different types of sweat glands in the skin. The numerous small sweat glands with terminal coiled tubules, which are widely distributed over the entire body and are particularly frequent on the palms, soles, and face are termed exocrine sweat glands. Departures from the usual structure of these sudoriferous glands occur in certain regions of the body. If we except the eyelids with their specialized sweat glands (of Moll) these locations are the mammary and axillary regions, the scrotum, the inguinal folds, the labia majora, and the anus. According to Robin certain parts of the side of the face contain these glands, where they are mixed

Fig. 6 Primary bilateral sweat gland carcinomata of the breasts in the same patient. In the right breast, the tumor is situated in the submammary fold, in the left breast the tumor is located in the axillary tail, both common sites of predilection for sweat gland cancers. Note the early marked attachment to skin.

inguinal apocrine glands even in normal conditions is different from sweat in other parts of the body. Another argument substantiating the relationship of these glands to the sex glands in common with the breast is the fact that the odor from these particular sweat glands provokes sexual stimulation in certain of the lower animals.

Apocrine sweat gland cysts of the axilla occur occasionally. Primary adenocarcinomata may occur in these cysts. The possibility exists that some of the primary cancers in aberrant breast tissue in the axilla may originate in apocrine sweat gland structures. Tiny sweat gland adenomata are often found in the skin of the scrotum and penis.

COMPARATIVE ANATOMY OF THE BREAST PHYLOGENETIC RELATION TO SWEAT GLANDS

The order of mammalia takes its name from these specialized cutaneous glands or mammae. The character and complexity of the breast

Fig. 17 Superficial ulcerating sweat gland carcinoma of the breast. The location and ulceration of this lesion are characteristic of but not peculiar to sweat gland carcinomata.

changes markedly from the primitive tubular glands of the lower orders of mammals to the human breast yet the fundamental structure and function remain essentially the same.

In the *Echidna*, which are *Monotremata* and the lowest order of mammals, there are no sweat glands on the entire body except a few in the immediate vicinity of the breasts. This remarkable anatomical fact strongly suggests that these surplus sweat glands are genetically related to the mammary glands in this animal. The deposit of large sweat glands under the areola in man is very likely a by-product in the evolution of the breast from these primitive types. The opposite condition obtains in the *ornithorhynchi* where the mammary organs have appropriated actually all of the sweat glands on the ventral body surface. In certain of the plated animals, the breasts are not developed as isolated discrete organs, but the secretion of a milk-like pabulum occurs over the major portion of the body surface and the young obtain their nourishment not by suckling but by licking this sticky secretion as it appears. In the *cetacea*, large muscle-walled sweat glands of the apocrine type are found near the mammary slits and on the vulva, although they occur nowhere else in the cetacean skin.

The excretory cutaneous glands of *amphibia* (e.g. frogs) are of the same two varieties as found in human skin: a common small gland secreting a clear watery or mucinous product and a larger specialized kind occurring only

in certain regions of the body and secreting and opaque white substance the analogue of true milk. The thumb gland which occurs only in the male frog has a functional and structural resemblance to the apocrine sweat glands. This thumb gland is a true sexual organ and enlarges considerably during the breeding season. It is a racemose tubular gland with a myo-epithelial cell layer similar in every respect to the apocrine glands of the human groin and axilla.

The breasts of marsupials such as the kangaroo are within a ventral pouch which harbors the immature fetuses. At the time these tiny immature fetuses attach them selves immovably to the nipples which nourish them the secretion of the breast is mucinous and the structure is primitive, as the young develop the breast and its secretion undergo corresponding modifications so that its structure is more complex (i.e. acinous rather than tubular) and the lacteal fluid approaches the composition of milk. It may be said therefore that the breast of the kangaroo during a single lactational period exhibits the various evolutionary changes seen in all the species of mammals, from the simple primitive gland of the sudoniparous type to the complex organ characteristic of the higher vertebrates.

Moles are said to have few sweat glands of either kind while the closely related shrews have a great sexual development of the large apocrine glands along the flanks. Creighton has called attention to certain accessory

sexual glands in the hippopotamus which secrete the so called bloody-sweat of that species. This fluid is a glairy substance the color of diluted port wine. The glands which secrete this liquid are branching tubular apocrine glands situated on certain parts of the dorsal surface of this animal. They are not accessory breasts but are phylogenetically related to the breasts.

Creighton has given a good conclusion which we shall quote in part. The true milk gland of the higher classes retains traces of its descent from sweat glands found either in the convolute tubular type of its rudiment and the muscular basement of its ducts or failing the latter in a basal layer of epithelial cells in the ducts. The muscle cells are very prominent in the more primitive types but with the development of acinous lobules this muscular element tends to be lost. What really distinguishes the human breast from the monotreme mamma (and the still more primitive sweat glands) is the acquisition or addition of acinous lobules in which the milk is secreted. The foundation of original tubules is retained for ducts."

SWEAT GLAND CYSTS AND ADENOMATA OF THE BREAST

Our knowledge of sweat gland structures in the breast and their histogenetic significance has been obtained largely through microscopical study of cystic diseases of the breast. The majority of investigators have studied 'sweat gland cysts' rather than

FIG. 20. Ulcerating sweat gland carcinoma of the submammary fold of the breast. Figures 20, 21, and 22 illustrate different stages in development of the sweat gland cancers of this region.

FIG. 21. Recurrent inoperable sweat gland carcinoma of right breast. The entire breast is involved by a diffusely infiltrating duct carcinoma. Once the sweat gland carcinoma is fully established, its local and systemic behavior is similar in almost every respect to the more common cancers of the lacteal gland.

sweat gland carcinomata on this account we shall give a detailed historical résumé of their researches.

The names of three men in particular are associated indelibly with the theory of sweat gland cysts and sweat gland carcinomata of the breast. Krompecher in Germany Creighton in England and Ewing in the United States. The latter has had great experience with these sweat gland cancers. It has been our privilege to review his abundant material. Mansell Moullin in 1881 described pea sized cysts in the mammary gland which were surrounded by parallel hoop-like rows of spindle cells. Although not identified as such, these cysts filled all the histological requirements of sweat gland origin. This is the first report we have been able to find in the literature wherein these peculiar structures were recognized. Juengst in 1884, described similar cysts accompanying an intracanalicular myxoma of the breast. It remained however for Krompecher in 1897 to identify these cystic structures as sweat gland cysts and to formulate the theory of histogenesis of sweat gland tumors. Dawson erroneously ascribes this original discovery to Borst who in 1904 demonstrated some mammary fibroadenomata which in circumscribed places showed large irregular pale cylindrical cells with compact homogeneous cytoplasm and nuclei of different size. These polymorphous high cylindrical cells with occasional giant nuclei were often arranged in stratified arcade like columnar epithelium. Von Saar in 1907 reported two mammary cysts lined with large

cells, containing a bright red fine grained protoplasm the cells never formed true vessel-bearing papillae although they were stratified in papillary tufts. Von Saar designated these cells as "pale epithelium" to distinguish them from the basophilic cells of the lacteal epithelium. Billroth found these peculiar cysts most commonly on the extreme periphery of the breast from which he inferred that a lobule here or there had failed to develop normally.

Krompecher's researches deserve a thorough summary. The cystic disease of the breast variously known as the *maladie kystique* (Reclus) cystadenoma (Schimmelbusch) and *mastitis chronica cystica* (Koenig) is neither a tumor nor an inflammatory lesion according to Krompecher but it is an anomaly of the mammary gland consisting of small cysts analogous to sweat gland cysts. This author designates this disease as hydrocystoma mammae multiplex and points out its morphological correspondence to the cysts of the axillary sweat glands. The first beginnings of this so called hydrocystoma of the breast consisting of such typical sweat gland cysts lined with pale epithelial cells and appearing grossly as bluish or greenish transparent vesicles from a millimeter to a centimeter in size are not infrequently found as Krompecher observed at autopsies in apparently normal female breasts. He found them in well developed as well as in involuted breasts and occasionally in adolescents. Even the male is not exempt from this disease as Krompecher has reported a typical case of sweat gland

Fig. 23. Papillary cystadenocarcinoma of breast sweat gland type. Low grade of malignancy (grade one plus or two minus) because of the degree of differentiation. It is quite radiosensitive. Its vulnerability is attributed to the character of the stroma rather than to the carcinoma cells *per se*. The tumor is mostly intracystic and intra ductal.

Fig. 24. Duct carcinoma ("comedo"-carcinoma) of sweat gland type. This histological variety of cancer is frequently found in lacteal ducts as well as in sweat gland ducts. In the latter case the ducts are gigantic and the carcinoma cells are larger and more conspicuously eosinophilic than in the lacteal duct cancers.

cyst of the breast in a male subject. The minute histological description of the cysts as given by Krompecher agrees in every particular with our own microscopical studies. The considerable size of the cells, the knob-like or clubbed protuberances of the cylindrical epithelium, the abundant compact homogeneous pale eosinophilic cytoplasm and the small round and occasionally giant nuclei comprise a characteristic microscopical picture. The peculiar pale epithelium of the cysts and tubules is very sharply differentiated from the lacteal epithelium and the excretory ducts of the breast. The cell boundaries are frequently indistinct and the adjacent cells in such cases appear to be confluent, forming giant polynuclear cells. Krompecher noted (and we have many times confirmed this observation) that the sweat gland epithelium in the breast is especially inclined to proliferate and form papillae. The majority of the papillary cystadenomata of the mammary gland originate from lacteal epithelium, but there are many others of the sweat gland type (Fig. 6). Krompecher found this pale sweat gland epithelium as the basic structure in 21 cysts, 12 benign fibro-adenomata, and 9 cancers in the group of 292 benign and malignant breast tumors comprising his material. In only 3 of the cancers however was he able to demonstrate the characteristic long

spindle cells running in parallel groups around the basement membranes.

Kuru observed this 'pale epithelium' in 3 breast tumors and emphasized the relative smallness of the nuclei. Von Saar likewise referred to the close similarity of the mammary cysts to the sweat glands in which the resemblance extends to the fine details of histological structure. Although we have emphasized the occurrence of sweat gland cysts in the microcystic variety of Reclus disease (non-inflammatory fibrosis) we do not mean to infer that they are pathognomonic for this disease because the majority of the cystic structures are lined by ordinary lacteal epithelium.

The specificity of sweat gland cysts in the breast is generally recognized by the French school. Roussy states in his recent textbook on cancer that there is normally a mixture of two kinds of glandular tissues in the breast, one the acinar glandular groups of the lacteal type and another of ramified ducts of the sudoriparous type lined by tall pyriform eosinophilic cells and occurring commonly in the axillary region. Letulle terms these sweat gland cysts of the breast 'idrosadenoides'.

Our youngest patient with sweat gland cysts of the breast was 26 years of age. Herzenberg found numerous pea-sized red nodules in both breasts of a stillborn infant

Fig. 5. Infiltrating sweat gland carcinoma of the breast. Typical structure of many of these cancers. Marked eosinophilia.

Fig. 36. Infiltrating papillary adenocarcinoma of the breast of the sweat gland type. Grade two plus. Radio-sensitive.

The nodules when examined microscopically proved to be cystic apocrine sweat glands.

We have seen sweat gland cysts and lacteal cysts immediately adjacent to each other and in several instances have been able by serial sections to trace these cysts and tubules to the point of anastomosis with lacteal ducts. Cheate likewise states that in serial section he has always been able to trace these cysts of the sweat gland type into the ducts of the breast. Semb found the pale and normal epithelium merging directly into each other in the same cystic duct of the breast. Although this may occur it is unusual more commonly an entire branch of a duct and its ramifications are completely involved in the process.

Presumably the factors predisposing to sweat gland cysts are the same as in lacteal cysts of the breast. Similar cysts have been produced experimentally in extramammary sweat glands these cysts are microscopically identical with the so called sweat gland cysts of the breast. The experiments of Schildach were successful in producing cysts of this type. He made semicircular linear incisions through the skin of the paws of narcotized cats, about the level of the excretory ducts of the sweat glands and parallel to the surface of the epidermis. The partially severed discs were then sutured back onto the paws the cats were given pilocarpine solution to stimulate the secretion of sweat and 3 to 9 weeks later were killed. On microscopical examina-

tion hydrocysts of the sweat glands had originated directly from the excretory ducts and resembled in every respect the sweat gland cysts found in humans, especially in the axilla and breasts.

In a recent article, Dawson vigorously attacks the hypothesis that these structures are of sweat gland origin. He asserts that the pale epithelium commonly identified as sweat gland epithelium is not related at any stage with sweat gland tissue and that it occurs in the breast too frequently to warrant the supposition of accidental inclusion as a developmental anomaly. He observed these cells in 130 breasts with malignant tumors and in 48 breasts with benign cysts all of which had the entire breast minutely examined microscopically in whole breast sections. We quote one of his arguments as follows. "An important and essential point to note is that in all cases this pale epithelium in the breast lines a definitely cystic structure, although the size of the cysts may vary within wide limits. Even the smallest pale structures are always larger than normal mammary acini." Dawson's assertion that these pale structures are found invariably associated with the formation of cysts in the breast is not substantiated by our studies (Figs. 5, 8 frontispiece, 9). This difference in size, although a distinguishing feature does not necessarily indicate that the so called sweat gland tubules are cystic and degenerated as compared with the smaller lacteal tubules. In the human

Fig. 27. See clinical photograph Figure 21. Alveolar sweat gland carcinoma of breast. Grade two. Moderately malignant. Some papillary structure.

Fig. 28. Medullary sweat gland carcinoma of breast. Grade two plus. With increasing anaplasia the cells tend to lose their eosinophilia; this change is more apparent than real because the nuclei are larger, the cell bodies are smaller, and eosinophilic cytoplasm is less conspicuous.

breast the lacteal tubules are largely excretory ducts and their lining epithelium is not highly functional whereas the primitive tubules such as the sweat gland structures are assumed to be lined by high columnar secretory cells. An analogy exists in the case of the developing kidney. The secretory units of the primitive kidney become the collecting tubules of the mammalian kidney and are morphologically quite different from secretory units such as the convoluted tubules. The sweat gland tubules have not differentiated sufficiently to be anatomically and functionally similar to the lacteal epithelium.

It is true that cell degeneration with the formation of cysts is more common in sweat gland structures in the breast than in the other mammary tissues. This is frequently the case in embryonal anomalies and should not be considered as evidence that all these sweat gland structures are degenerative. Many sweat gland cysts contain cell detritus made up of the desquamated pale epithelium.

Dawson presents another argument for the degenerative theory by calling attention to the fact that pale eosinophilic glandular epithelium has been observed in the ovary, uterus, prostate, and kidney all of which are the site of possible cystic degeneration. Dawson furthermore states "The onset of the pale change is post-proliferative and an evidence of a checked and receding epithelial activity." We have previously stated that sweat gland cysts and tubules are character-

istically prone to form papillary ingrowths yet we have never seen these structures prior to the supposed change wherein the epithelium becomes eosinophilic. If Dawson's observations are true we should see this many layered proliferating epithelium before it degenerates and becomes eosinophilic. Furthermore all stages of the transition should be visible and we would not expect to see the uniformity in structure which the sweat gland tubules and cysts constantly show in serial section. It is our belief therefore that the eosinophilia and other anatomical characteristics of these cells precede and accompany the proliferative changes.

There are numerous other theories extant to explain the presence of these structures in the mammary gland. McFarland has considered them to be residual (i.e. non involuted) lactation acini, although many pathologists have discovered them in non lactating virginal and even infant breasts. Prym considers the pale epithelium as metaplastic mature breast tissue predominantly acinar tissue.

SWEAT GLAND CARCINOMA OF THE BREAST

Krompecher was the first to observe the cancerous transformation of the pale epithelium characteristic of sweat gland tubules and cysts. He commented on the active participation of the pale epithelial cells of these cysts and the intracanalicular cystadenomata in

the carcinomatous proliferations. The eosinophilic cells form stratified layers and papillae within the cysts occasionally even blocking the lumina and forming pale epithelial nests and alveoli. According to this author these relations demonstrate that both intracanalicular cystadenomata and true carcinomata can originate directly from the pale epithelium of the sweat gland cysts.

Berka studied the intracystic papillary formations in sweat gland cysts and considered the process as something intermediate between metaplasia and anaplasia. Furthermore he noted a close resemblance of these large pale eosinophilic cells to certain atypical elements in large cell carcinomata of the breast without however showing definite malignant growth. Charteris studied whole sections of 48 breasts removed for carcinoma. He saw these pale cells of the sweat gland type and even noted the development of carcinoma from them.

(Other pathologists are definitely opposed to the theory that these sweat gland cysts with intracystic proliferations are precancerous and even deny that carcinoma ever developed from this pale epithelium. Von Saar in particular states that no direct transformation of these cells into carcinoma has ever been confirmed.

Dawson calls attention to the rarity of sweat gland carcinoma of the skin: he found only one specimen of this type in 13,500 pathological lessons studied. Because of this fact he cannot understand why the malignant possibilities of these so called sweat gland structures should be so much enhanced when they supposedly form a normal inclusion in the breast substance. Contrary to this view it is our opinion that sweat gland ducts and cysts in the human breast should be even more prone to undergo malignant degeneration because of the well known tendency of aberrant primitive and embryonal structures to become malignant.

Dawson has classified the conflicting opinions concerning the nature and possibilities of the 'pale epithelium' into two definite groups, namely (a) The pale epithelium indicates a proliferative change with a more or less definite possibility of later malignant development (Krompecher Borst Ewing Cheate

and Cutler Creighton) (b) The pale epithelium indicates a proliferative change with later and progressive degeneration (Von Saar Theile Deaver and McFarland Blood good Prym).

Although Theile once observed an actual transition from pale epithelium to carcinoma he states that he found in the pale epithelium no specific kind of cell 'but only a degeneration form originating under certain external conditions, which are distinguished from the normal gland cells by a stronger growth energy (formation of epithelial papillae) and secretory activity (vacuoles) or even by a briefer period of life. We cannot comprehend how a cell can exhibit 'stronger growth energy' when it is degenerating. It seems more likely that the eosinophilic character and the large size of the pale cells are characteristic of the sweat gland epithelium in as much as they persist in the majority of cases after malignant change has supervened. In Cheate and Cutler's experience this peculiar staining property of the pale cell disappears when the neoplastic stage is manifested. A study of our material shows that this change occurs especially when the carcinoma becomes increasingly malignant and exhibits anaplastic tendencies. Thus we have several specimens in which a fairly well differentiated sweat gland carcinoma has the large pale eosinophilic cells in certain regions, while in other portions of the same carcinoma the cells are smaller more hyperchromatic, less differentiated and presumably more malignant.

It is our opinion that the sweat gland features of these structures in the mammary gland may be found in all pathological stages, from the normal breast microcystic disease of the breast benign tumors, and precancerous intraductal papillomatous processes, to carcinoma. A recent specimen in our selection exhibits all of these stages in sweat gland cysts: an intraductal papillary cystadenoma and a true sweat gland carcinoma. It is unlikely that the cysts, the intraductal cystadenoma, and the carcinoma have all undergone degeneration simultaneously and uniformly throughout. Mitotic figures found in the eosinophilic sweat gland cells verify their active participation in cell multiplication and

the growth of the carcinoma. Dawson maintains that these mitotic figures represent "agonal mitoses" in dying cells.

The first detailed and accurate description of the growth and microscopic pathology of sweat gland carcinoma of the breast was reported by Ewing. This author states that a considerable proportion of mammary cancers arise in sweat glands of the breast, in his material, this proportion is in the neighborhood of 25 per cent. We have recently analyzed a group of 166 histologically verified primary operable carcinomata of the breast and in this group 41 or practically 25 per cent, were of the sweat gland type. The sweat gland cancers of the breast may be either cystic or solid. Aside from their peculiar distribution in the breast there are few distinguishing features of this type of mammary cancer except that they are usually more yellow than other mammary carcinomata. Ewing attributes this yellow color to xanthomatous changes which are more frequent in sweat gland cancers than in other varieties.

Our material is the same from which Ewing made his original observations. He found that the majority of the papillary cystadenocarcinomata and the glandular adenocarcinomata with cuboidal clear cells and basophilic cytoplasm develop from the lacteal ducts whereas the sweat gland ducts of the breast give rise chiefly to papillary and adenocarcinomata in which the cells are columnar rather than cuboidal. These cells are predominantly eosinophilic. Some of the comedo carcinomata or duct carcinomata are of this type although in such cancers the ducts are usually much larger than in the case of carcinoma of the lacteal ducts. The tendency of the sweat gland carcinomata to form papillary structures is in keeping with this same inclination of the sweat gland cysts and tubules.

The eosinophilia of the cytoplasm in the well differentiated sweat gland carcinoma testifies to the sudoriparous origin of these cells which is further emphasized by the presence of certain cells of the myo-epithelial type arranged in a comb-like fashion at the periphery of the neoplastic nodules. These cells are found only rarely and then only in those cancers which are not invasive and do

not destroy the integrity of the surrounding breast tissue. The myo-epithelial cells are either not reproduced in the rapid growing sweat gland carcinomata, or if they are present, they are not recognized as such.

Some of the sweat gland carcinomata in our collection are made up of clusters of large alveoli lined with one or occasionally two rows of opaque eosinophilic cells with supporting cells lying on a well defined basement membrane. The morphological and staining characteristics which distinguish them from other carcinomata of the breast may be lost in the anaplastic varieties, this is quite evident in studying the metastases from such cancers. Except for these properties which we have enumerated the sweat gland carcinomata of the breast have much the same structure as other mammary cancers, indeed, we find that the bulky adenocarcinomata the comedocarcinomata the papillary intraductal and intracystic adenocarcinomata, the medullary carcinomata the carcinoma simplex and even scirrhous carcinomata of the breast are represented in this group although the distribution is not the same as in the case of carcinomata arising from the lacteal ducts.

We have shown in our clinical analysis of 81 cases of sweat gland carcinomata of the breast that this tumor is more frequently adherent to the skin than is the ordinary breast cancer. Pain occurs in only 8 per cent of the general group of mammary cancers whereas in the sweat gland carcinomata of the breast it is the predominant symptom in 34 per cent of the patients. Approximately two-thirds of these carcinomata were situated in the periphery of the breast, where the apocrine sweat glands are most abundant. We sometimes find these sweat gland carcinomata in the subareolar region adjacent to the great ducts near the nipple.

CLINICAL REPORT OF EIGHTY-ONE SWEAT GLAND CANCERS OF THE BREAST

Age. The average age of 2,663 patients with mammary cancer who applied to the Memorial Hospital was 51 years; this same age was also the average for the 81 patients with sweat gland carcinoma of the breast. The oldest patient with any type of mammary

Age group	Carcinoma of the Breast		Sweat Gland Carcinoma of the Breast

cancer was 90 years and the youngest 17 years while the eldest patient with sweat gland cancer of the breast was 84 years and the youngest 19 years of age. The diagnosis in both cases was "primary operable carcinoma of the breast."

Race The distribution of these patients according to racial origin is not particularly significant. There were 27 Americans 14 Irish, 7 Hebrews 6 Russians 5 Negroes 3 Germans 2 Italians 2 Newfoundlanders 2 Polish 1 Norwegian 1 Swede 1 Swiss 1 Hungarian and 1 Turkish patient. The complexion of 24 of these patients was recorded of which 95 per cent were brunettes. Sweat gland cancers of the breast occur more frequently in women whose skins are oily and contain large pores, so we would expect a predominance in brunettes because of their coarser skin textures.

History of lactation Data concerning lactation was available for 67 patients of whom 60 per cent had nursed one or more children of the 16 non-lactating breasts 40 per cent were in single women. Seven patients (12 per

cent) stated that the cancerous breast had been non functional due either to abscess formation caking insufficient secretion or to the fact that it was more convenient to nurse the baby on the other breast. Sixteen patients (20 per cent) had experienced one or more interrupted pregnancies. One woman had 4 full term pregnancies and 12 miscarriages. No conclusion can be drawn from this study concerning the influence of lactation in the production of sweat gland carcinoma.

Trauma Twenty two patients gave a definite history of trauma to the affected breast while 45 others asserted that they could recall no injury to their breasts. The character of the trauma varied however 15 women or 68 per cent of those with breast injuries, stated that a single blow was considered by them to be the cause of the cancer. One patient had sustained the trauma 12 years prior to the detection of the tumor and 3 had discovered a tumor very shortly after the date of injury. The average time elapsing between the trauma and the recognition of the cancer was 2 years. We do not ascribe any etiological importance to the history of trauma recited by these patients for 2 reasons the interval of time was usually too great and the presence of pre-existing tumors could not be ruled out in the 3 instances in which tumors appeared suddenly after injury. In our experience a single trauma has never caused cancer of the breast. We, therefore believe these histories of single trauma to be of little or no significance. Two women attributed their cancers to chronic irritation by sharp corset steels this condition was not unusual several years ago when high ribbed corsets were in vogue as sweat gland cancers of the breast are frequently situated in the mammary fold. Although but 2 women gave histories of chronic irritation from ill fitting corsets impinging on the lower margin of the breast, we believe this type of chronic irritation may not infrequently serve as an exciting cause of sweat gland carcinoma in the lower breast segment.

First symptom In 77 cases the history contained a definite statement concerning the first symptom observed by the patient. Fifty seven patients (76 per cent) gave the discovery of a lump in the breast as their first

symptom and this parallels our experience in a survey of the first symptom in 1 000 cases of mammary carcinoma in general. Fifteen of these patients had inoperable cancers at the time of diagnosis. In 10 per cent of the cases, a discharge from the nipple preceded the discovery of the tumor as compared with 15 per cent in the survey previously mentioned. Eight per cent noticed pain as the first evidence of disease either in the affected breast or in the arm and shoulder of the same side which is the identical figure in the 1 000 breast cancers surveyed including all types. The 6 per cent remaining had miscellaneous first symptoms such as an increase in the size of the breast, ulceration of the mammary skin, tumefaction of the nipple, or bulky axillary lymph nodes.

Size of tumor. Six of the primary operable carcinomata (14 per cent) were greater than 6 centimeters, 25 (57 per cent) were 3 to 6 centimeters in diameter and 13 (29 per cent) were less than 3 centimeters in size. Of the primary inoperable carcinomata 6 were greater than 6 centimeters in diameter 8 measured 3 to 6 centimeters and only 2 tumors were smaller than 3 centimeters in size. The operability of any particular sweat gland cancer was never determined by the measurements of the primary tumor but we are recording them to afford complete clinical data.

Location. Dependable data concerning the location of the tumor is available in 74 cases of this series. The accompanying diagram (Fig. 15) shows the regional tumor sites in these patients. In one-sixth of all the cases the growth occurred in the central segment immediately beneath the areola. Eleven per cent of the sweat gland cancers were located in the axillary tail of the breast 33 per cent in the upper outer quadrant and 10 per cent in the submammary fold. This division is somewhat arbitrary as many tumors which are really located in the axillary extension of the breast spoken of in this paper as the "tail" are recorded to be in the upper outer quadrant. It seems significant that slightly more than half of these tumors are situated in the upper outer quadrant and margins of the breast, which regions contain numerous large apocrine sweat glands.

Rate of growth. Prior to this study it was believed at the Memorial Hospital that sweat gland cancers of the breast were relatively less malignant than some of the other histological varieties but this opinion was not confirmed by our analysis of the cases. For example, 50 per cent of these cancers grew with great rapidity and the 2 oldest patients, aged 84 and 82 years had rapidly growing tumors. The rate of growth in 31 per cent of the cases was moderately rapid. The youngest patient, aged 19 years, had a slow growing tumor as did 19 per cent of the entire group. Contrary to our observations on mammary cancers in general the sweat gland carcinomata of the breast are apparently not of more rapid growth in young subjects.

Pain. Sensory disturbances varying from slight mastalgia to severe pain in the breast, often radiating to the shoulder and arm were noted by 28 patients (34 per cent). Sixteen of these patients (or one-third of the primary operable groups) experienced pain before treatment was given. Similar sensory disturbances were found in 9 patients (48 per cent) with primary inoperable breast cancers of this type. In the general group of breast cancers studied at the Memorial Hospital, pain has never been a frequent symptom, occurring in only 8 per cent of primary operable cancers. We attribute the unusual frequency of pain in sweat gland cancers of the breast to early skin attachment and ulceration.

Skin adherence and nipple retraction. Thirty-three (71 per cent) of the primary operable sweat gland cancers of the breast were adherent to skin. The cause of this early and frequent skin attachment probably lies in the superficial location of these tumors. The nipple was retracted or fixed in only 50 per cent of the cases, due to the fact that so many of these tumors were situated at the margins of the breast where they could not exert traction on the nipple. Six of the nipples in patients with tumors centrally located were deeply ulcerated.

Metastasis to lymph nodes. Thirty-two (64 per cent) of the patients with primary operable sweat gland cancers had metastases (proved histologically) in the axillary lymph nodes.

The primary tumor was situated in 40 per cent of these cases in the upper outer quadrant of the breast or the axillary tail. Ten patients (33 per cent) with primary inoperable sweat gland cancers had axillary metastases but not supraclavicular. In 6 other inoperable cases (12 per cent) both axillary and supraclavicular lymph nodes were involved. Fifty-eight per cent of the patients with recurrent sweat gland cancers of the breast had metastases in the supraclavicular lymph nodes which is the usual experience with mammary carcinomata in general.

Metastasis to lungs and pleura. Thirty-seven per cent of these women with inoperable sweat gland cancers of the breast and 25 per cent of those with recurrent lesions had pulmonary metastases demonstrable on roentgenograms.

Metastasis to bone. Only 7 patients (8 per cent) presented definite evidence of metastasis to bone. One young woman under 40 years of age had pre-operative X-ray therapy, local excision of the tumor, interstitial irradiation by platinum filtered radon needles and post-operative X-ray irradiation for an operable sweat gland cancer; she developed pulmonary and bone metastases 1 year later. The rapid extension of the disease to osseous structures parallels our experience with many young women similarly treated for other forms of mammary cancer. Another young patient came to the Memorial Hospital with widespread skeletal involvement but no local recurrence 4 years after a radical mastectomy had been done. Another woman aged 48 years with a slowly growing operable carcinoma and axillary metastases developed bony metastases and died only 6 months after a radical mastectomy. An aged woman of 84 years had a rapidly growing sweat gland cancer which originated beneath the nipple and early became ulcerated. She had metastases to bone at the time of admission in spite of which she lived 4 years after local excision of the tumor and external irradiation with X-rays and radium element pack.

End-results. Of the 50 patients with sweat gland cancers of the breast, classified as 'primary operable' 21 are dead, 20 are living and 9 have been lost to our observation.

The 9 who have been lost to observation, either returned to a foreign country or moved to a distant state. One was known to be well for 6½ years, and another for 5 years after treatment. Of those who died, the average length of life from onset of symptoms to death was 3½ years and the average length of life after the institution of treatment was 2½ years. Five patients lived less than a year after therapy was started, the shortest time being 2 months. Thirty-six of the patients having primary operable sweat gland cancers of the breast were treated prior to January 1927. In this group 5 have been lost to further observation and 16 (44 per cent) are alive and well 5 years or more after treatment. Twenty of these patients were treated prior to January 1925 and 8 or 40 per cent are living and well 7 years after treatment. Seven patients with primary operable cancers of this type were treated before January 1920 (13 years ago) and 2 of these (28.5 per cent) are living, apparently cured of the disease at this time. These percentage figures are slightly higher than the end result percentages recently computed at the Memorial Hospital for primary operable mammary cancers of all histological types viz. 5 year survival without evidence of disease in 217 patients treated by radical mastectomy with pre-operative and postoperative irradiation 41 per cent 7 years, 35 per cent 10 years, 22 per cent. We may conclude from these comparative statistics that the degree of malignancy and prognosis following treatment is practically the same for sweat gland cancers of the breast as it is for the general group of mammary cancers. If a large group of sweat gland carcinomata of the breast could be surveyed with respect to end results, the comparison would be more significant.

In the primary inoperable group consisting of 19 patients, 14 are dead, 4 are living and 1 has been lost to observation. One of the patients who died went into shock immediately after a palliative operation and lived less than 48 hours. The average duration of life after the onset of the disease was 3½ years. 2 other patients in this series stated that a lump was felt in the breast 20 years before admission to the Memorial Hospital. The average duration

of life after the initiation of therapy in these inoperable cases was 21 months, the longest being 5 years and the shortest 4 months. Our 4 patients who are now alive were first treated 9 years, 2 years, 19 months, and 8 months ago. The one who has lived 9 years without a recurrence was 57 years old when first seen in November, 1922. She had a bulky fungating sweat gland cancer with ulceration of the nipple and metastasis to axillary lymph nodes. A roentgenogram of the chest was reported to have shadows suggestive of carcinomatous metastases, however there has been no change in this picture to date. She was treated by radical mastectomy following a pre-operative X ray cycle.

There have been 12 patients with recurrent sweat gland cancers of the breast, 6 are dead and 6 are living. The average time from the onset of the primary disease until death was 4½ years and the average length of life after treatment of the recurrent lesion at the Memorial Hospital was 10 months. The time elapsing between the operative treatment of the primary tumor and the application at Memorial Hospital because of a recurrence averaged 18 months for the 12 patients, the shortest being 18 days and the longest 4 years.

SUMMARY

The human breast develops as a modified apocrine sweat gland. Apparent sweat gland tubules and cysts occur in the normal adult breast where they anastomose with the interlobular lacteal ducts. The characteristic features which distinguish the mammary sweat gland tubules from the lacteal ducts are: constant eosinophilia of the cytoplasm, an inner layer of high columnar cells, the occasional presence of myo-epithelial cells surrounding the tubules and the tendency to form intratubular and intracystic papillary tufts. The anatomical and staining characteristics of these cells persist through all the transitional phases of normal sweat gland tubules, cysts, intracystic papillomas, adenomas, and carcinomas.

Evidence is presented to substantiate the theory that sweat gland carcinomata of the breast may develop from pre-existing sweat gland tubules, cysts and papillary adenomata.

The various stages in this transition have been seen. Except for the peculiar properties of sweat gland structures in the breast which we have enumerated, the sweat gland carcinomata of the breast have much the same structure as other mammary cancers, e.g. we find that the bulky adenocarcinomata, the comedocarcinomata, the papillary intraductal, and intracystic carcinomata, the medullary carcinomata, the carcinoma simplex and even scirrhous carcinomata of the breast are represented in this group.

Sweat gland cancers of the breast occur more frequently in swarthy brunettes whose skin has large pores and oily, coarse texture. Their regional distribution is mostly on the periphery of the breast particularly in the axillary tail and submammary fold. The frequency of pain, skin adherence and ulceration are significant clinical features of sweat gland cancer of the breast. The degree of malignancy and the prognosis following treatment is practically the same for sweat gland cancers of the breast as it is for the general group of mammary cancers.

NOTE.—The authors wish to express their appreciation to Dr. James Ewing, Dr. Elise L. Esperance, Dr. W. C. Langston, and Dr. Henry McEl. Knowler for their aid in the completion of this study.

PEPTIC ULCERS ARTIFICIALLY PRODUCED IN THE HUMAN BEING

A. JAMES WALTON M.S., F.R.C.S. B.Sc. LONDON ENGLAND

CLINICAL and experimental observation has now made it evident that the presence of the gastric juice is an important factor in the production of gastric ulcers. If the juice is allowed to act upon the mucosa of the duodenum ileum or jejunum in an undiluted state an ulcer almost invariably develops. Such a condition may be seen around the islands of gastric mucosa occasionally found in a Meckel's diverticulum or in a gastric pouch experimentally made and united with the intestines (1).

The fact that the gastric juice does not invariably lead to ulceration of the normal stomach or of the jejunum after gastro-enterostomy has been the subject of prolonged investigation. One of the factors of importance is believed to be the dilution of the gastric juice which usually occurs in the stomach. Removal of the salivary glands (3) or the formation of an œsophagostomy opening through which all the saliva escapes is not invariably followed by ulceration nor does such regularly occur in patients with a complete œsophageal obstruction.

Matthews and Dragstedt also failed to produce ulceration in dogs after the performance of a gastrostomy and an œsophageal fistula whereby sham feeding was carried out and the secretion of acid was induced without being diluted by the food which escaped through the fistula. If however, the alkaline secretion of the bile and pancreatic juice was removed, ulceration occurred in a high percentage of cases. Removal of these alkaline secretions was easily accomplished by excising the pylorus closing the duodenal stump, dividing the jejunum just below the duodenojejunal flexure anastomosing the cut end of the stomach with the distal end of the jejunum and the proximal end of the jejunum into the ileum close to the ileocecal valve. Similar operations and results were performed by Mann (1).

These experiments were to a certain extent vitiated by the fact that the animal developed

a cachexia and then died probably owing to the effect of transposing two such important digestive secretions so low down in the ileum. When bile and pancreatic fluid were allowed to enter the intestines higher up ulceration was less common. Matthews and Dragstedt have shown that this is probably due to regurgitation of the alkaline secretions for if regurgitation was prevented by an ingenious method they devised the ulceration became more common.

The artificial formation of a pancreatic fistula which can be performed upon an animal kept alive by daily injections of salt solution is also followed by chronic ulceration. The important factor therefore in preventing the gastric juice producing an ulcer in a normal animal is the neutralizing effect of the pancreatic juice and bile.

The effect of such factors are much more difficult to determine in the human being. Although gastro-enterostomy is usually performed for chronic ulceration in which the acid is usually high gastrojejunal ulceration does not in the hands of most surgeons, occur more frequently than in 3 per cent of the cases. In my own series of 1247 gastro-enterostomies, such ulceration occurred in 25 that is 2 per cent. Moreover, after an adequately performed partial gastrectomy, my own experience agrees with that of Lord Moynihan that such ulceration is practically unknown. In my own series of 466 partial gastrectomies it occurred in only one case in which it was known that gastric resection was insufficient.

In the human being the conditions experimentally produced in animals rarely occur but it is interesting to note that the Roux operation of partial gastrectomy which most closely produced these conditions, in that the pancreatic juices entered the jejunum well below the end-to-side anastomosis, has now been universally abandoned as it was followed by so high a percentage of gastrojejunal ulceration. In the 2 following cases the

conditions experimentally produced in animals were somewhat closely simulated and the resulting formation of chronic ulceration becomes of considerable clinical interest.

CASE 1. Development of peptic ulcer after partial pancreatectomy and partial gastrectomy

A.E.L. male aged 38 years, had suffered with attacks of epigastric pain from 1906 until 1913. The attacks would last for about 2 months and for 1 year they had been getting longer. The pain came on shortly after food, was severe in nature and often indeed agonizing. It was associated with vomiting which gave some relief to the pain. On June 23, 1913 he was operated upon by another surgeon who found what he thought to be a large carcinomatous ulcer in the middle of the stomach. In performing a partial gastrectomy the surgeon realized that the neck of the pancreas had been cut through and practically the whole of the body removed with the ulcer. Pathological investigation showed that the ulcer was benign. This operation was apparently followed by the formation of a subphrenic abscess which was drained and the patient then steadily improved and put on weight. In 1916 however his symptoms began to return. He then had attacks of radiating pain through the epigastrium to the lower abdomen. The pain occurred relatively late after food and was relieved by food. It was associated with vomiting which also gave considerable relief. In June, 1921 he was admitted to Hospital and his test meal showed free hydrochloric acid 15 per cent and a total acidity of 53. An X-ray investigation was performed and was said to be suggestive of a jejunal ulcer. He was treated by dieting. In September, 1922 he sought my advice as his symptoms had been getting worse. The pain would now wake him at night and the last attack had persisted for 6 weeks. His appetite had been getting poor and he had been losing weight. On examination there was some tenderness in the epigastrium but no definite tumour. His hydrochloric acid was now 12 per cent and his total acidity 45. The X-ray examination showed a constant meniscus in the region of the gastrojejunal opening. An operation was performed on September 20, 1922 and a gastrectomy of the Billroth II type was found. In the center of the anastomosis was a very large indurated ulcer. Practically no pancreatic tissue could be found. A more extensive partial gastrectomy was performed, only about half an inch of the lesser curvature being left. The excision was planned not only to remove a large portion of the stomach but also the loop of the jejunum attached to it. An anastomosis was carried out between the cut end of the stomach and the two cut ends of the jejunum by the Polya method, the afferent loop being brought to the lesser curvature and the efferent to the greater curvature. The pathological report stated that there was a chronic progressive peptic ulcer in the jejunum and very numerous oxyntic cells in the gastric mucous

membrane. The patient made an uninterrupted recovery and has been seen at frequent intervals in my follow-up department since. He is now quite free of symptoms, is taking all food and is able to live a perfectly normal life.

CASE 2. Development of peptic ulcer after cholecystenterostomy for pancreatitis

J.G. male aged 52 years, was first seen on July 9, 1929. For 4 months he had noticed that he was becoming jaundiced and had had some shivering attacks. For some 3 months there had been itching of the skin of the whole body which was relieved only by soda baths. His appetite had remained good, and there had been no pain of any sort. In spite of a careful diet and medical treatment his jaundice had been progressing. He had lost a stone in weight in the last few months. On examination he was found to be a thin jaundiced, restless man. The liver could be felt uniformly and smoothly enlarged. There was no tenderness. The gall bladder could not be felt. The stools were clay colored. An operation was performed on July 12. The pancreas was found to be uniformly hard and enlarged, and there were no localized nodules. The head and body presented a similar consistency. The gall bladder was distended and tense but tucked away under the enlarged liver. There was no evidence of any secondary growths and no stone or growth could be felt in the common bile duct. The stomach was smooth and the duodenum was tied down in the right lumbar region. It was found that the gall bladder could only be approximated to the duodenum or stomach with some difficulty and it was, therefore, thought wiser to bring a loop of small intestine about 18 inches from the duodenojejunal flexure up through the mesocolon. The gall bladder was emptied, and thick, tenacious bile was removed and an anastomosis was then performed between it and the loop of the small intestine. The patient made very good progress and his jaundice rapidly decreased. Three months later he was feeling very well. On January 24, 1930, he complained of having had indigestion for 2 weeks and on March 18, he was found to be very anemic and complained of epigastric pain passing to the back. This was severe and occurred late after food. He was admitted to hospital and the stools were found to be very black and contained a large amount of blood. There was a considerable degree of anemia. The test meal showed free hydrochloric acid 16 per cent and a total acidity of 75. An X-ray investigation showed a clear lesser curvature of the stomach and no delay at the pylorus. It was interesting to find that the gall bladder filled rapidly and easily with the barium meal and presented a picture of a big duodenal pouch. There was no evidence of a chronic duodenal ulcer. The patient was kept in bed and treated medically and improved very considerably and in April, 1930, was free from symptoms and his anemia had recovered. In spite of the alkaline treatment, he had another attack of melena in January 1931 and became very anemic. He was seen by a physician and kept in bed on a

strict diet and made some improvement but in August 1931 it was again noted that he had blood in the stools. On September 15 he was readmitted to hospital complaining of a considerable amount of pain and tenderness, a blood examination showed only two and a half million red blood corpuscles. On September 18 1931 a second operation was performed. Dense adhesions were found around the gall bladder and anastomosis and behind this could be felt a hard indurated area in the first part of the duodenum. The pancreas was smooth and very hard. It was thought that the duodenal ulcer was unquestionably due to removal of the alkaline juices, which were probably diminished by the presence of the pancreatitis, from the duodenum to the jejunum. The efferent loop from the cholecyst enterostomy was therefore freed and brought up to the stomach, an anterior gastro-enterostomy being performed. The patient stood the operation very well and made an uninterrupted recovery. His pain disappeared the blood count rapidly improved and he ceased to pass blood in the stools. He has been seen from time to time in the follow up department and the last note September 1932 states that he is very well is on a full diet with no pain the anaemia has completely disappeared and he is living a normal life.

In the first of these cases the pancreatic secretion was greatly diminished by the extensive pancreatectomy and thus failed to neutralize the gastric juice, although this was reduced by the partial gastrectomy. In the second case the pancreatic secretion was not only probably in part reduced by the pancreatitis but was made to enter the intestine at a considerable distance from the duodenum so that the gastric juice was not neutralized. Reduction of this juice in the one case and its adequate neutralization in the other brought about a complete cure.

OSTEOCHONDRITIS OF THE GROWTH CENTERS

A FURTHER CONSIDERATION¹

J. C. PICKETT M.D. AND MAXWELL HARBIN M.D. F.A.C.S. CLEVELAND, OHIO

THE purposes of this paper are (1) to present three cases of osteochondritis of the growth centers, (2) to discuss and correlate the clinical and pathological aspects of the disease, (3) to present a method for the investigation of the pathogenesis of this condition and (4) to urge the necessity of prolonged avoidance of weight bearing in certain types of the disease.

Although the literature is rich in case reports and discussions of osteochondritis there has been an almost complete absence of pathological studies. During the past year four unusual cases have been studied and from three of these biopsies were obtained. These cases are presented with the thought that by a continuance of such studies the pathogenesis of osteochondritis may eventually become more clearly understood.

Harbin and Zollinger in 1930 reviewed the pathological changes that occur in the various ossification centers of the human skeleton and called attention to the fact that a wide variety of terms are used to designate the same type of lesion occurring in different places. They proposed to simplify the confused nomenclature that has arisen because of the application of proper names to the disease in the various growth centers, by the use of the term "osteochondritis." In conjunction with the name of the growth center involved. The name of a disease should be descriptive of the pathological changes involved and the term "epiphysitis" was deemed unsatisfactory because the disease is not confined to the epiphysis. It is recognized, too that the term osteochondritis is not entirely descriptive, inasmuch as its inflammatory character is not fully established. The selection of a suitable name must await further pathological studies.

Zemansky in 1928 gave a comprehensive summation of the literature regarding the pathological changes occurring in the capital epiphysis of the femur. Although all of the

cases which he reported had some findings in common they varied in detail. He concluded that the pathological changes occurring in this disease in the hip were extensive subchondral necrosis of bone and marrow with complete destruction of the epiphyseal line fragments of dead bone surrounded by richly vascularized granulation tissue fibrous tissue replacement of necrotic areas with osteoid formation from fibrous tissue and pre-existing bone lamellae dilated blood vessels in the under surface of the cartilage. In the 11 cases which he summarized the epiphyseal line was present in cases of short duration, while in those cases extending over a longer period it was at least partially destroyed. Later Lippmann reported a case focusing his observations principally on those occurring in the round ligament. In this he demonstrated obliterative thickening of the vessels with hemorrhage and edema of the ligament itself. In the case reported by Harbin and Zollinger there were no pathological changes seen in the specimen removed for biopsy. Vignard also reported 2 cases in which no change was observed. It is probable that in these latter cases the biopsy simply failed to include definite diseased areas.

CASE 1. A white girl, aged 4 years, was originally admitted to the Rainbow Hospital with the complaint of stiffness in joints and weakness. She had been a full term, normal infant. Breast feedings were given for the first year with the addition of cod liver oil and orange juice. The first teeth appeared at 7 months, and the remainder were normal in time of appearance. The child talked at 18 months and walked 1 month later. At that time it was noted by the mother that movement in all of the joints was limited, and that when the child walked the feet were turned outward at right angles to the body. In addition, the ankles, knees, wrists, and elbows were larger than normal, and she could walk only a short distance before becoming tired. The family physician said that she was underdeveloped, and he increased the amount of cod liver oil. She was seen later by another physician who made a diagnosis of severe rickets, and she was treated following this with ultraviolet lamp

and given viosterol. She had always been subject to frequent colds and was underweight. It was noted by the parents that she frequently perspired about the forehead. The mother felt that she had shown little if any general improvement and that in addition she was becoming more round shouldered. There had been no gastro-intestinal upsets and the bowels were always regular.

Fig. 6 Non-ossified epiphysis of femur comprised of hyaline cartilage which is the seat of fibillar degeneration and extensive vascularization. $\times 70$

The 4 other children in the family were in excellent health. Parents were small in stature.

The physical examination revealed an underdeveloped and somewhat undernourished child with a generalized muscular weakness who was unable to stand without support or to walk for more than a short distance unaided (Fig. 3). The knees were flexed slightly when she walked. The head, eyes, ears, nose and throat were normal. The teeth were normal and the tonsils were not enlarged. The heart and lungs were normal, and there was no gross evidence of rickets in the bony thorax. The spleen and liver were not palpable. The extremities showed weakness and atrophy that was most marked in the legs. The thenar and hypothenar eminences of both hands were flattened. The proximal interphalangeal joints of the third and fourth fingers of both hands were enlarged and fusiform in shape. The wrists were large and broad. There was no muscular atrophy of the arms or forearms, and movement in all the joints, except the right wrist, was within normal range. The right wrist showed marked spasm and limitation especially on hyperextension. The internal malleoli of both ankles were enlarged with thickening about the joints. The knees were enlarged with periarthritic thickening but they were not tender. The left hip showed normal flexion with 5 degrees of adduction and 15 degrees of abduction. There was 5 degrees of internal rotation and 35 degrees of external rotation. The right hip showed unlimited flexion with 45 degrees of motion in both abduction and adduction. Internal rotation was limited to 10 degrees with 45 degrees external. Motion was painless. The usual reflexes were present and equally active. The spine showed a moderate dorsal kyphosis with rounded shoulders.

Fig. 7 Articular cartilage showing active vascularization with formation of trabeculae of osteoid. Zone of proliferate cartilage is not unusual and the zone of provisional calcification is not apparent. Extensive degeneration, laceration and vascularization of cartilage. $\times 200$.

Röntgenograms showed the dorsal and lumbar vertebrae to be irregular in outline mainly in their anterior portions (Figs. 2 and 3). The intervertebral spaces were maintained throughout but the bodies were flattened. The capital epiphyses of both femora were flattened and irregular (Fig. 4). This was most marked on the left where there was fragmentation and some evidence of migration of the head toward the trochanter. The necks were very short and greatly thickened but the epiphyseal lines could be seen. A similar process was seen in the heads of both humeri, the condyles of the femora and the patella. These changes were also seen but to a less extent in the ankles, wrists, and the metacarpals.

Laboratory examination showed no abnormalities of the urine or blood. The blood Wassermann was negative. The basal metabolic rate was increased 31 per cent. The blood serum calcium was 10.6 milligrams per 100 cubic centimeters and the phosphorus was 4.5 milligrams.

The patient was placed in the dorsal decubitus position on a hyperextended Bradford frame because of the dorsal kyphosis. Free use of the extremities was encouraged by physiotherapy including exercises in the underwater gymnasium. A fairly constant range of temperature from 37.5° C. to 38° C. (rectal) was observed. She showed slight general improvement, and, on December 9, 1931, an exploration of the left hip was carried out through an anterior incision.

At operation the capsule was found to be normal. The head was definitely enlarged and the neck was short and thick but there were no other gross abnormalities. The acetabulum was normal in appearance. Tissue for biopsy was removed from the region of the epiphyseal line including the adjacent tissue (Fig. 5). The tissue was softened but well vascularized.

Fig. 8. Early change in the right hip. There is only slight flattening of the head and shortening of the neck (Case 2)

Motion was restricted only by a crinolin spica and convalescence was uneventful without febrile reaction. Aerobic and anaerobic cultures were negative.

The specimen submitted for pathological examination consisted of a cylinder taken from the head of the femur so as to include the entire thickness of the articular cartilage, the bony epiphysis, and the epiphyseal plate of cartilage. The bony changes were not remarkable and appeared to be secondary rather than primary. In spite of the marked deformity of the head of the bone seen roentgenologically, the general pattern and structure of the trabeculae were normal. The density varied with osteoporosis predominating. The marrow was not unusual except in the subchondral zone where it was fibrous. There was no necrosis and no hemorrhage. The articular and epiphyseal chondro-osseous junctions were very irregular. The primary spongiosa in both situations was poorly calcified and preponderantly of osteoid. The zone of provisional

Fig. 9. Presents a marked degree of progression of the disease in the capital epiphysis on the right with fragmentation of the head (Case 2)

calcification was irregular and poorly defined. Enchondral vascularization was very pronounced and the penetrating blood vessels were found at greater distances from the marrow than usual. These vessels were surrounded by collars of osteoid and frequently by wide zones of proliferating fibroblasts. Despite the vascularization the enchondral ossification was focal and generally retarded. This retardation seemed best accounted for by the severe degenerative changes present in the cartilage. Foci of degeneration and necrosis were scattered throughout the epiphyseal and articular cartilage and in the latter there were deep fissures and tears, sometimes reaching the chondro-osseous junction (Fig. 6). Areas of resting cartilage were interposed between areas of cartilaginous hyperplasia and the hyperplastic foci were almost invariably associated

Fig. 10. Diagram indicating the point of removal of tissue for biopsy (Case 2)

Fig. 11. Articular cartilage, Case 2 including a group of ingrowing marrow vessels at the edge of an area of cartilaginous degeneration. There has been focal absorption of the matrix which has taken on a fibrillar character. Such areas are especially well vascularized but without ossification. X65

Fig. 12. Presents very slight change in the right hip. The head is slightly flattened. (Case 3.)

with disintegration of the matrix. Much of the vascularization with accompanying fibroblastic proliferation appeared to be in the nature of a repair process, when there had been dissolution of the original hyaline cartilage (Fig. 7).

Since the foregoing procedure was carried out, the patient has been given general hygienic treatment including ultraviolet lamp therapy and cod liver oil. Her posture has improved slightly but her general condition shows but little change.

CASE 2. A white boy of 8 years was admitted to Lakeside Hospital in January 1931 with the complaint of pain in the right hip and a limp of 3 months duration. There was an indefinite history of a fall at the beginning of the illness. Examination at that time showed a few carious teeth and enlarged tonsils. The extremities were normal except for the right hip. There was flattening of the buttock and 1 inch atrophy of the thigh. Palpation revealed no peri-articular thickening or tenderness. Motion was limited in abduction and internal rotation. Roentgenograms of the hip showed some flattening of the capital epiphysis with definite increased density in a portion of it (Fig. 8). Urine and blood studies were normal. The blood Wassermann reaction was negative, and the tuberculin test, 1:1000, was negative. The patient remained in bed but showed no clinical improvement in the hip, and a plaster spica was applied on February 18, 1931. This was removed after 6 months, but after he was allowed up a limp was immediately noted. He denied any pain, and the roentgenogram showed only a slight increase in density of the epiphysis.

In February 1932 he was readmitted to the hospital with the complaint of a dull aching pain in the right hip which always appeared after walking

Fig. 13. Shows rapid progression of the disease with irregularity and fragmentation of the head but no appreciable thickening of the neck. The epiphyseal line is irregular. (Case 3.)

or playing for a short time. Examination revealed the right leg to be 0.5 inch shorter than the left. The right buttock was flat, and there was 2 inches atrophy of the thigh. Motion at the hip showed abduction of 25 degrees, flexion of 25 degrees, internal rotation of 5 degrees, and external rotation of 10 degrees. There was no palpable tenderness or thickening. Roentgenograms showed progressive flattening and fragmentation of the capital epiphysis on the right (Fig. 9). The blood Wassermann reaction was negative, and the tuberculin test, 1:1000, was negative. The serum calcium was 21.2 milligrams per 100 cubic centimeters of blood and the serum phosphorus was 4.9.

On February 16, 1932 an exploration of the right hip was carried out through an anterior incision. The synovia was thickened and hyperemic. There was increased fluid in the joint. The head of the femur was large and smooth and capped over a shortened neck. Across the top of the head was a groove that corresponded to the position of the upper margin of the acetabulum as it rested against the large head. The acetabulum was of normal size and depth but too small for the head. There was no evidence of a round ligament. The epiphyseal line was identified and two blocks of tissue were removed from the epiphysis with an osteotome (Fig. 10). Aerobic and anaerobic cultures were taken from the joint and the depths of the wound from which the tissue was removed.

The gross specimen showed what appeared to be islands of cartilage in bone tissue. Microscopically there was marginal thickening of the articular cartilage. Scattered through the cartilage were

degenerative foci ranging from fibrillation to necrosis. In the fibrillary areas around the small blood vessels the matrix was absorbed and the vessels were surrounded by actively proliferating fibroblasts to produce small cellular islands (Fig. 11). The chondro-osseous junction was quite irregular and the bony lamella thin and interrupted. The most conspicuous change seen was simple rarefaction of the matrix, and in some instances this was associated with the granular deposition of calcium. Independent islands of bone with fatty marrow were seen in the cartilage. The synovia was thrown into polypoid folds and the lining cells were hyperplastic. Beneath the surface the synovia was richly vascularized and there was considerable lymphocytic infiltration that was characteristically perivascular. *Staphylococcus albus* grew in aerobic and anaerobic cultures.

Convalescence was uneventful and the patient's condition has remained about the same. Roentgenograms show a slight increase in the amount of fragmentation. He has been given cod liver oil and ultraviolet lamp therapy as a general measure and has not been allowed to bear weight on the involved extremity.

CASE 3. A white boy, aged 4 years, was first admitted to Rainbow Hospital August 1931, because of a painful right hip. The onset of the complaint had occurred very suddenly in June 1931, when he first complained of pain. Soon after this a limp was noted by the members of his family. This lasted for about 1 week and then disappeared; however, it recurred about 10 days later and was so severe that he could not walk. Roentgenograms showed very slight flattening of the capital epiphysis on the right (Fig. 12). He was placed on a Bradford frame with the leg in traction. By November 18, 1931, all physical signs had disappeared, and he was allowed to go home. He returned 1 month later with reappearance of all symptoms with increased severity and in addition a history of *night cries*. His past history revealed only an attack of mumps, frequent colds, and sore throats.

The physical examination showed a moderately well developed but somewhat undernourished white boy. The examination was essentially normal except for the right lower extremity. There was no shortening of the right leg but there was 1 inch atrophy of the thigh. Palpation revealed no tenderness, but there was marked spasm with any attempt at motion. Internal rotation and hyperextension were completely limited and abduction was limited to 10 degrees. Roentgenograms showed definite flattening of the capital epiphysis with some fragmentation (Fig. 13). The neck was hairy and irregular with two small punched out areas in the diaphyseal side of the epiphyseal line. The urine was normal. The Wassermann test was negative; tuberculin test, 1:1000, was negative. The serum calcium was 10.4 milligrams per 100 cubic centimeters of blood and the serum phosphorus was 4.7 milligrams.

Fig. 14. Diagram showing the points of removal of the tissue for biopsy (Case 3)

Following admission he was placed in traction and the pain and spasm grew less. On January 30, 1932, because of the unusual appearance the hip was explored through an anterior incision. It was our impression before operation that we were dealing with an osteitis rather than an osteochondritis. The capsule was found to be thickened and hyperemic with some increase in fluid. The head and neck showed no gross abnormalities and the acetabulum appeared normal. A block of tissue was removed from the epiphyseal line with an osteotome (Fig. 14). The tissue did not appear to be as well vascularized as normally and the material was softer than usual. Microscopic study showed foci of degeneration in the cartilage which were in places myxomatous and in others fibrillar. Such degenerate foci were sharply circumscribed (Fig. 15) and occasionally associated with vascularization and beginning calcification. There was a moderately severe osteoporosis. Cultures showed no growth.

Convalescence was uneventful and the patient was again placed in traction. Gradually all spasm and limitations have disappeared and at present there is no limitation of motion. He has not been allowed to bear weight on the extremity for almost 5 months, however. Recent roentgenograms show some slight fragmentation of the epiphysis.

The fourth case is presented to show the striking similarity of arthropathy of the tarsal scaphoid to osteochondritis.

CASE 4. A white boy, aged 12 years, was admitted to the hospital with the complaint of swelling of the feet. At the age of 3 the patient had an attack of diphtheria and some time following this the mother noticed that his legs were weak and that it was more difficult for him to walk than it had been previously. This condition remained about the same until he

Fig. 15. Epiphyseal plate showing normal hyaline cartilage at the top separated from the degenerate cartilage at the bottom by an area of cartilaginous regeneration and proliferation. Such spontaneous repair was not a prominent feature, the degenerate areas usually being vascularized and collapsed. X85.

was 10 when it was noted that he was walking on his toes with the feet turned in. In August 1931 the patient noticed, while running barefoot that the right foot was swollen and a little tender. The swelling persisted up until the time of admission to the hospital, without pain. There was no history of injury, chills or fever or of poliomyelitis. His general health had always been good.

The mother and father were cousins. There were four children in the family. The oldest had had no difficulty. The next oldest boy had been in the hospital repeatedly with a complaint somewhat similar to that of this patient. In addition he has shown marked loss of sensation with trophic disturbances in the lower extremities. The youngest child, a girl, is normal except for a cardiac lesion thought to be rheumatic in origin.

The physical examination showed a fairly well developed, somewhat undernourished, white boy whose examination was not remarkable except for the lower extremities. The legs showed atrophy with complete relaxation of the longitudinal arches in both feet. The tendo achillis on each side was tight and prevented dorsiflexion of the foot even up to a right angle. The legs were equal in length and the muscle power below the knees was very poor except for the gastrocnemii. He was unable to invert the foot at all and the peroneals were only

Fig. 16. The right foot in the lateral position shows compression and fragmentation of the scaphoid. A lateral film of the left foot illustrates the same character of change in the head of the astragalus. (Case 4)

moderately strong. There was swelling with peri-articular thickening over the dorsum of both feet, most marked over the right in the region of the scaphoid where there was local heat and redness, but there was no pain or tenderness in either foot. When he walked he rose on his toes with the knees flexed. The toes and knees were pointed inward to maintain balance. He walked with a peculiar shuffling scissors-like gait as he lurched from side to side and swung the arms to keep from falling. The reflexes in the arms, abdominals, epigastrics, and cremasterics were normal. In the lower extremities the reflexes were hyperactive with both patellar and ankle clonus. The latter was a constantly sustained response, the former only occasionally. There was a Babinski response to plantar stimulation on both sides and the Romberg test was positive. The cranial nerves showed no involvement and the eye-grounds were normal. There was weakness of the lower abdominal muscles. There was no change in sensation over any portion of the body and the joint sense was normal. There was no ataxia, no intention tremor, no past pointing. Speech was difficult. The vibratory sense was not lost.

Röntgenograms of the feet (Fig. 16) showed a destructive process involving the right scaphoid and the anterior portion of the astragalus. On the left the astragalus alone was involved. The bony arches were flattened. The spine showed no abnormality.

Laboratory studies showed the urine and blood to be normal. The Wassermann reaction was negative. The tuberculin test, 1:1000 was negative. The serum phosphorus was 4.3 milligrams per 100 cubic centimeters of blood and the serum calcium was 10.3 milligrams. The spinal fluid was clear and colorless. The Pandy test was negative and there were no cells. The Wassermann test was also negative.

The patient was kept in bed over a period of weeks until the redness and swelling had disappeared.

Since he has been allowed to walk his condition has changed very little except that under training his gait has somewhat improved. We believe this to be a case of *hereditary family spastic paraplegia* with changes in the bones of the feet resembling osteochondritis but probably an arthropathy.

The first patient presented several rather perplexing problems. She was the first patient that we have seen or of whom we have heard in whom the condition was generalized. When first seen she had the appearance of having polyarthrits with enlargement and stiffness of all the joints. The involvement of all the epiphyses and particularly the appearance of the hands suggested achondroplasia but there was no disparity in comparison between the length of the torso and the extremities. The normal blood serum calcium and phosphorus, absence of certain stigmata and the roentgenographical appearance helped to rule out rickets.

Harbin and Zollinger reported one family in which four individuals showed osteochondritis of the spine. Such observations together with this case cause one to consider again both hereditary and metabolic factors in the etiology in these individual cases.

The second patient was given the benefit of immobilization over a period as long as that in which many cases have begun to show clinical improvement. It is evident that the process was not healing since with weight bearing the condition progressed and the signs returned once more. The roentgenographical picture was then striking as compared with the earlier one showing only slight flattening and areas of increased density. At operation there was found evidence of inflammatory change in synovia, joint, and bone. Four cultures were taken in all two aerobic and two anaerobic, and all showed *staphylococcus albus*. This is the first positive culture that we have ever obtained from a patient with osteochondritis, it suggests again a consideration of infection as an etiological factor but only in this individual case. The condition, therefore, may be one of osteitis rather than osteochondritis.

The third patient was immediately immobilized with the acute onset. At that time we felt that such a long period of immobilization was not necessary and he was allowed to

run about after the acute signs had disappeared. Within a short time the acute symptoms returned and it is evident from the roentgenograms that the disease had progressed rapidly. It is of interest that the clinical signs and symptoms have again disappeared but he has not been allowed to bear weight at this time.

It would appear that the pathological picture in these cases varies from that described by previous observers in that instead of describing and discussing a different condition we are seeing merely different phases in the pathogenesis of the same condition. Beyond doubt, all of the cases described except possibly Case 2 can be clearly classified as osteochondritis of the capital epiphysis from the appearance of the roentgenograms. We did not remove the entire head in any case as we felt that in such young individuals such treatment is too radical. It is true that in older individuals we see frequently an arthritis of the hip which we ascribe to an old osteochondritis. In such cases excellent results have followed the Whitman reconstruction operation. In growing children however we believe that removal of the head will aid in preventing later arthritis. It will also prevent further growth from this important center and for that reason is not a procedure of choice.

The pathological changes observed in all 3 cases were similar in that the cartilage both articular and epiphyseal was the seat of the most striking alteration. The osteoporosis of the epiphysis could be explained by the inactivity rather than as a feature of the disease. The irregularity in density of the osseous head was thought to be due to the irregular retardation of enchondral ossification and to the production of osteoid rather than bone. The asymmetry and non-development (apparent destruction) of the head seemed better accounted for as a failure in new bone formation rather than as a destruction of already formed bone inasmuch as the former was seen to be true while there was no necrosis or unusual osteoclasia to indicate the latter. This lack of ossification was related to if not caused by a deterioration of cartilage, which was focal and which ranged

from simple fibrillation to necrosis of cells and dissolution of matrix. The cartilage was so severely altered that despite the relative inactivity of these individuals deep fissures and tears through the entire articular plate were observed. The cause of the cartilaginous degeneration was not apparent although faulty nutrition is obviously suggested. Harbin and Moritz called attention to the presence of interlacunar canaliculi in the matrix of hyaline cartilage and suggested the importance of these canaliculi in the dissemination of nutritive substances throughout cartilage. The primary defect responsible for the imperfect ossification of the epiphysis may rest in the lack of permeability of the cartilaginous matrix with subsequent degeneration so as to inhibit proper enchondral ossification. The fact that the cartilage was so richly vascularized does not militate against this hypothesis because the presence of the blood vessels may represent an attempted compensation or may be regarded as a reparative process for the necrosis.

Microscopic evidence of inflammation was not seen either in bone or cartilage. The chronic hyperplastic synovitis observed in one case was not explained.

We must conclude that the necrosis and repair of bone described by Zemansky was either a different phase of the disease than seen by us or a manifestation of greater severity. The latter belief seems more tenable if one accepts the hypothesis of the repaired nutrition to explain the cause of the epiphyseal change. Whereas in the cases seen by us the cartilage was damaged to the extent of being unsuitable for enchondral ossification it is not difficult to consider the same process becoming extended to include the bone and cause the necrosis described by other authors.

In order to complete the pathological picture the entire pathogenesis must be seen and studied. This can be accomplished if com-

plete clinical and laboratory study of all cases is made followed by a biopsy according to the Key block method. It will then be possible to correlate pathological change with the gross and roentgenographical appearance. Large numbers of such cases will eventually result in a varied picture which if viewed with sufficient perspective may allow us to gain a clear conception of the etiology of osteochondritis. We have reason to think that years are necessary for healing to take place in this disease and that alone would seem to account for a great part in the variation of the histopathology.

SUMMARY

1. Three cases of osteochondritis are reported with clinical findings and associated pathological change. One of these cases showed a generalized involvement of growth centers, the first of its kind ever to have been published.

2. An attempt is made to correlate the varied pathological reports from the literature.

3. A method is offered as an aid in obtaining the complete pathology and the etiology is discussed.

The authors wish to thank Dr. Alan R. Moritz for the preparation of the photomicrographs.

THE RELATION OF MATERNAL METABOLISM TO
INFANT BIRTH WEIGHT

WILLIAM F MENGERT M.D., PHILADELPHIA

From the Department of Obstetrics and Gynecology School of Medicine State University of Iowa

THE factors which influence intra uterine development of the fetus and its weight at birth remain obscure although the problem has been attacked both in man and in experimental animals from many angles.

The assumption of a relationship between maternal weight and maternal diet during pregnancy to infant birth weight seems so probable that it has been studied exhaustively (1 4, 5 6, 7, 8, 13, 17 22) The results however have been for the most part negative and it is now generally believed that diet plays no rôle of consequence in influencing the birth weight of the newborn There is experimental evidence to show that healthy well nourished rats produce litters of greater total weight than smaller animals fed on a deficient diet (7 8) but the variation is so small as to be quite negligible The opinion of present day investigators may best be summed up in the statement of Franz and Zondek, quoted by Jonen (4) "The fetus develops without consideration of the maternal organism and like a parasite withdraws what it finds necessary to its composition" If the maternal organism does not provide the materials necessary for fetal development damage to or death of the fetus results with subsequent abortion (4, 5 8 17 22) but without noticeable effect on birth weight

Other maternal factors which have received attention include age (1 7), social status (15) national disturbances such as war (14) number of previous pregnancies (7 15 24), whether or not previous offspring have been suckled (1) length of pregnancy (2 7 18), seasonal variations (1 16 24) primiparity versus multiparity (9 15) and the duration of the menses (9, 21) With the exception of the last named such factors bear only an insignificant relationship to birth weight, influencing average infant weights less than 100 grams. The older the mother the greater the birth weight, and the more unfavorable the social status and the greater the national dis-

turbance the more unfavorably fetal development is affected If previous offspring were suckled birth weights decrease in subsequent pregnancies. In general, infant birth weight is greater in summer than in winter The birth weight tends to increase with the number of pregnancies

Matarsse, and Szenes and Mondré, listing 400 and 739 human births respectively point out the correlation between length of menstrual period and infant birth weight and show that weight and length of the child at birth are directly proportional to the duration of the menses in days

The nutrition of the father has been studied in animals (8) but no relationship was observed The action of the various vitamins has been investigated in attempts to clarify the problem (8, 12 16 17 22 23), but the results have been no more convincing than other starvation experiments along the same lines Depletion of vitamins produces fetal damage (8 17, 22) and abortion while an increase in vitamin D in the maternal diet influences intra uterine development favorably (12 22) and is an aid in hindering habitual antepartum fetal death (12)

The placenta has been studied from the standpoint of iron content (3) and of architectonic structure of the blood vessels (20) The iron content of 100 grams of placenta was correlated with birth weight and was found to vary directly with the birth weight in children below normal limits, reaching its highest value in children in the usual range (2,800 to 3,500 grams) and then decreasing in the higher weight groupings Shordania found that there was a tendency to lower placental and fetal weights if there was great diffusion of the main vessels of the placenta

PURPOSE OF PRESENT STUDY

The present study was suggested by certain unpublished data indicating sectional differences in average birth weights and was

Fig. Scatter diagram of distribution of basal metabolic rates of 303 pregnant women and weights of their infants at birth. Horizontal axis, maternal basal metabolic rates. Vertical axis, Infant birth weights in grams. Nine infants weighing less than 2000 grams are not included. Dots enclosed by circles represent two determinations falling at the same point on the chart. Note that there is no valid relationship between the two variables.

planned to determine whether a relationship exists between maternal basal metabolic rate and infant birth weight. With Matarese and Szenes and Mondré claiming that prolonged menstrual periods correlate with greater infant birth weights and with menorrhagia known to be associated with moderate hyperthyroidism it is suggested that low basal metabolic rates should correlate with large and high rates with small babies.

METHOD

Basal metabolic rates, each reading comprising a trial and an actual test were done on 212 normal pregnant women taken in order of admission to the Obstetrical Service of the University Hospital. A few of these women

were occasionally admitted some weeks before delivery so that in an exceptional instance a reading was obtained as early as 80 days prior to the onset of labor, although the majority were made within 30 days of labor. The determinations were made as soon after admission as the women were adjusted to routine hospital life and were done by the indirect method based upon oxygen consumption with the respiratory quotient assumed to be 0.82 and the Roth Benedict apparatus being used. They were done according to the routine hospital technique and were interspersed with the daily work of the metabolic laboratory insuring reasonably consistent data, although the emotional element was not necessarily completely controlled. Only a

TABLE I.—MATERNAL BASAL METABOLIC RATES AVERAGED ACCORDING TO INFANT WEIGHT GROUPINGS

Birth weight of infants—grams	Average maternal B.M.R. (calculated arithmetically)	Number of cases	Range of maternal B.M.R.
2,000 to 2,499	-11.0	1	-4.0 to -33.0
2,500 to 2,999	-11.8	30	-4.3 to -47.3
3,000 to 3,499	-12.8	43	-5.8 to -51.8
3,500 to 3,999	-9.9	5 ^a	-7 to -25.0
4,000 to 4,499	-11.2	13	-5.7 to -30.3
4,500 to 4,999	-1.3		-13.0 to -20.3

^a Nine infants weighed less than 2,000 grams and were not included in this table. As there is no relationship between the two variables, infant birth weight and maternal basal metabolic rate, as demonstrated.

single reading was obtained on each patient although the advisability of repeated tests is well recognized.

RESULTS

The maternal basal rates as determined ranged from minus 17.7 to plus 37.5 while the birth weights of the babies varied from 750 to 4,514 grams. Evaluation of the collected data was carried out in three ways.

The infant birth weights were arranged arbitrarily into six groups ranging from .000 to 4,999 grams in steps of 500 grams and the average maternal basal metabolic rate calculated for each group (Table I). Also the metabolic rates were arranged in six groupings and the average infant birth weight computed for each group (Table II). Nine infants weighed less than 2,000 grams and were not included in either table. Neither arrangement of the data shows any significant differences among the computed group averages.

A scatter diagram (Fig. 1) was drawn with maternal basal metabolic rates plotted along the horizontal axis and infant birth weights along the vertical axis. The lack of a relationship between basal metabolic rate and infant birth weight may readily be seen by a glance at the graph.

Finally correlations were computed for the series of 212 patients and a resulting coefficient of $r = 0.057$ —a probable error of 0.046 obtained. Such a low correlation indicates definitely that so far as the data of the present

TABLE II.—INFANT BIRTH WEIGHTS AVERAGED ACCORDING TO METABOLIC RATE GROUPINGS

Maternal B.M.R.	Average I.B.W., grams	Cases	Range of infant birth weights—grams
-20.0 to -24.9	3,501.0	4	3,634 to 3,910
-25.0 to -29.9	3,374.0	13	3,045 to 4,200
-30.0 to -34.9	3,313.3	73	3,050 to 4,230
-35.0 to -39.9	3,417.3	70	3,574 to 4,484
-40.0 to -44.9	3,413.3	25	3,415 to 4,515
-45.0 to -49.9	3,397.3	3	3,115 to 4,006

Nine infants weighed less than 2,000 grams and were not included in this table. As there is no relationship between the two variables, maternal basal metabolic rate and infant birth weight, as demonstrated.

study go no relationship exists between maternal basal metabolic rate and infant birth weight.

CONCLUSIONS

No predominating factor influencing infant birth weight has yet been demonstrated.

No relation was demonstrated between single basal metabolic rate determinations done by the indirect method on 212 normal, healthy pregnant women and the birth weights of their children.

THE EFFECT OF PERITONEAL IRRITATION ON THE EMPTYING TIME OF THE GALL BLADDER AND STOMACH

A. W. OUGHTERSON, M.D. AND J. C. MENDILLO, M.D., NEW HAVEN, CONNECTICUT
From the Department of Surgery, Yale University School of Medicine

THE rôle of the sympathetic nervous system in relation to the altered function of various portions of the gastrointestinal tract has in recent years attracted much attention. The work reported in this paper was undertaken for the purpose of establishing a functional relationship between the autonomic nervous system and the gall bladder if such existed and to determine whether this effect was one of excitation or inhibition. The response of the gall bladder to remote peritoneal irritation offered a means of obtaining further evidence regarding the functioning of the gall bladder and also the possible relationship of the sympathetic nervous system to this organ. The effect of such peritoneal stimulation on the gall bladder was studied by means of roentgenograms following the intravenous injection of sodium tetradiodophthalein. The filling and emptying time as well as the ability of the gall bladder to concentrate the dye were observed and this correlated with the emptying time of the stomach as determined by roentgenograms following a barium meal.

That the gall bladder has a relatively rich nerve supply of both medullated and non-medullated fibers has been well established but the connections of these fibers and particularly their relations to the vagus and splanchnic nerves have not been clearly defined from an anatomical viewpoint. The functions of this abundant nerve supply have been the object of much investigation, but, unfortunately due partly to the variety of experimental procedures used, there have been many conflicting results. The earlier studies were chiefly directed toward the vagus and splanchnic nerves in an effort to establish their specified functions as regards the gall bladder, and the earlier investigators such as Heidenhain and Doyon believed that the splanchnic nerves were motor to the gall bladder. At a later date Courtade and Guyon,

Bainbridge and Dale, Lieb and McWhorter, Westphal and others concluded that the vagus was the motor nerve to the gall bladder. Bainbridge and Dale also showed that splanchnic stimulation resulted in relaxation of the gall bladder. Freese concluded that the splanchnics contained both motor and inhibitory fibers. Mann in summing up the literature in 1924 concluded that 'as is seemingly true with the other viscera all the motor and inhibitory fibers do not run in the same nerves but some of each are found in the vagus and splanchnic nevertheless the vagus is mainly motor and the splanchnic mainly inhibitory to the gall bladder. All of the data were based on direct observation of the exposed or isolated gall bladder or on changes in pressure within the biliary system. In most instances the nerves were stimulated electrically and in some the changes were based on the action of drugs.

The advent of a means of visualizing the intact gall bladder permitted an experimental approach much more closely simulating normal physiology. Whitaker was the first to use this means of studying the nervous control of the gall bladder. His method was to inject iodized oil into the gall bladder following which he stimulated the nerves both centrally and peripherally. His conclusions were that the vagus and splanchnic nerves played no essential rôle in the emptying of the gall bladder. Boyden (3) observed that adrenalin was very effective in producing a diminution in the size of the gall bladder shadow, and interpreted this as a contraction of the gall bladder musculature although Burget thought this escape of bile could be accounted for by relaxation of the duodenum induced by the adrenalin. Copper, Kodoma and Graham (7,8) studied the effects of electrical stimulation of the vagus in dogs following the intravenous injection of suitable dyes for visualizing the gall bladder. Their results suggested some

intestinal tract. The work here reported likewise indicates that the emptying of the gall bladder is under the control of reflex pathways associated with other portions of the gastrointestinal tract and it is probable that dysfunction and stasis of the gall bladder may be due in part to inhibitory reflexes arising from chronically diseased portions of the gastrointestinal tract. Likewise certain cases of postoperative vomiting may be explained as the result of gastric dysfunction by means of these reflex pathways.

SUMMARY

1 The effect of remote stimulation of the peritoneum on the emptying time of the stomach and gall bladder has been studied in dogs by means of roentgenograms

2 Such stimulation results in a delay in the emptying time of both the stomach and gall bladder

3 It is suggested that certain types of gastric and gall bladder dysfunction and stasis may be explained on the basis of these reflex pathways

THE ABSORPTION FROM TRAUMATIZED MUSCLES¹

R. A. DANIEL, Jr. S. E. UPCHURCH AND ALFRED BLALOCK NASHVILLE, TENNESSEE

THE toxemia theory of shock assumes that an absorption of toxic products from the injured area is responsible for the diminution of blood volume and the decrease in blood pressure. The experiments described in this paper were undertaken to determine the relative absorptive powers of traumatized and normal tissues. Underhill, Kapsinow and Fisk in studying burns found that "after a short latent period absorption from the burned area is much slower than it is under normal conditions."

The studies were performed on dogs. They were deeply anesthetized by sodium barbital (0.3 gram per kilogram of body weight) that was given intravenously. The animals gave no evidence of pain during the experiment and were killed at its completion. Muscle injury was produced by striking the thigh repeated hard blows with a hammer. The blows were not directed over the femoral vessels. The skin was not torn and the femur was not broken. The duration of the traumatization was approximately 5 minutes. Thirty minutes after the traumatization was terminated the pbthalein or strychnine was injected into the injured muscle. The arterial blood pressure was recorded throughout the experiments.

Experiments with phenolsulphonepbthalein The studies with pbthalein included three groups of experiments: (1) those in which the dye was injected into the muscle of the anterior abdominal wall of normal dogs, (2) those in which the dye was injected into the anterior abdominal wall of dogs which had had one extremity traumatized and (3) those in which the dye was injected into the injured muscle of a traumatized extremity. A catheter was placed in the bladder at the beginning of the experiment and the bladder was emptied. Each animal received 12 milligrams of pbthalein shortly after 350 cubic centimeters of tap water had been introduced by stomach tube. The pbthalein excretion was determined at hourly intervals for the first 6 hours following its introduction. Further determinations were

usually performed 6 and 18 hours later. The results of these experiments are given in Table I.

From this table it is to be seen that there was very little variation in the dye elimination by the different normal animals. Most of the dye had been absorbed and excreted 4 hours following its injection. The average amount of pbthalein recovered in the urine during the entire course of these experiments on normal dogs was 94.5 per cent of that injected. The percentage of pbthalein recovered from the urine of dogs which had one extremity traumatized and the dye injected into the anterior abdominal wall varied from 80 to 97, the average being 87.5 per cent. The elimination of the dye was slower in these experiments than in those in which no trauma was carried out. A greater amount of the dye was recovered in the second hour than in the first.

When the dye was injected into the center of the traumatized area a smaller proportion of it was recovered. The average elimination was 53.8 per cent of that injected. Also the rate of elimination was considerably slower.

From these experiments it is evident that the absorption of the dye from injured muscle as compared with that from normal muscle is markedly diminished.

Experiments with strychnine The time of the onset of convulsions, the character of the convulsions and the effects on the animals were noted in 3 types of experiments: (1) those in which strychnine was injected into the anterior abdominal wall of normal dogs, (2) those in which the drug was injected into the anterior abdominal wall of dogs which had had an extremity traumatized and (3) those in which strychnine was injected into the injured muscle of a traumatized extremity. The amount of strychnine that was injected in all experiments was 10 milligrams per kilogram of body weight. The results of these experiments are given in Table II.

It is to be seen in this table that five normal anesthetized dogs received an injection of

TABLE II.—INJECTION OF STRYCHNINE

Dosage 10 mgms. per kilogram of body weight

Exp. No.	Time between injection and first convulsion	Character of convulsion	General remarks
Normal dogs. Strychnine injected into anterior abdominal wall			
1	7 min.	Very severe	Dog died 1.45' after injection during a severe convulsion. B. P. 118 mm. Hg just before fatal convulsion.
2	21 min.	Severe	Survived. Dog killed 5 hours after injection
3	10 min.	Very severe	Dog died 2'25" after injection during a severe convulsion
4	13 min.	Severe	Dog survived. Killed 4 hours after injection
5	7 min.	Very severe	Dog died during severe convulsion 35 minutes after injection
Traumatized dogs. Strychnine injected into anterior abdominal wall			
1	10 min.	Severe. Short duration	Died 5'20" after injection. Death not preceded by convulsion
2	10 min.	Moderately severe	Died 2'12" after injection, probably of shock
3	6 min.	Severe	Died during severe convulsion 27 minutes after injection. B. P. was 110 mm. Hg just before fatal convulsion
4	16 min.	Severe	Died 2'20" after injection during a convulsion
5	11 min.	Severe	Died 30 minutes after injection
Traumatized dogs. Strychnine injected into injured area			
1	No convulsions		Gradual fall of B. P. Died of shock 34 minutes after injection
2	2 hours, 20 min.	Few mild jerks	Died of shock 16 hours after injection
3	5 hrs.	One mild convulsion	Died of shock 5 hrs. after injection
4	1 hr. 30 min.	9 mild convulsions	Gradual fall of B. P. Died 2'25" after injection, probably of shock
5	1 hr. 10 min.	6 mild convulsions	Gradual fall of B. P. Died 2 hrs. after injection, probably of shock

strychnine into the anterior abdominal wall. The time between the injection and the first convulsion varied from 7 to 21 minutes in the different experiments. Three of the animals died after having severe convulsions. The 2 remaining dogs had severe convulsions but survived.

In 5 experiments one of the posterior extremities was traumatized and strychnine was injected into the anterior abdominal wall. The onset of convulsions varied from 6 to 20 minutes following the injection. The convulsions were quite severe in four of the five experiments. All the animals died. In two experiments, death occurred during a severe convulsion. Death was probably due to the trauma in 2 animals which lived for more than 3 hours following the injection. There were no convulsions for a considerable period preceding the death of these 2 animals. In the remaining experiment in which the animal lived 50 minutes, death occurred 10 minutes

following a severe convulsion and it was not known whether the animal died as a result of the administration of the strychnine, or the trauma, or both.

No severe convulsions were produced by the injection of strychnine in the 5 experiments in which it was introduced into the injured muscle. Four of the animals had mild convulsions. The time separating the injection of strychnine and the onset of convulsions varied from 1 hour and 10 minutes to 3 hours. The animals which had convulsions lived from 2 hours and 5 minutes to 16 hours following the injection of strychnine. Death in all instances was almost certainly due to the trauma and not to the strychnine.

These experiments show that the absorption of strychnine from the anterior abdominal wall is altered very little by trauma to an extremity. On the other hand, strychnine is absorbed very slowly when it is introduced into the traumatized area itself.

SUMMARY

The absorption of phenolsulphonephthalein and of strychnine by deeply anesthetized dogs has been studied under three experimental conditions (1) normal dogs in which the injections were made into the anterior abdominal wall (2) dogs with a traumatized extremity in which the injection was made into the anterior abdominal wall and (3) dogs with a traumatized extremity in which the injection was made into the injured muscle. There was not a great deal of difference in the absorption of the solutions that were injected into the

anterior abdominal wall of normal dogs and of dogs with a traumatized extremity except for a slight delay in the latter group. On the other hand the absorption of the phenolsulphonephthalein and of the strychnine that was injected into the traumatized area itself was greatly retarded.

THE CONCEPTION PERIOD IN NORMAL ADULT WOMEN

V. G. MILLER, M.D. C. H. SCHULZ, M.D., D. W. ANDERSON, M.D. HOSKINT, LINDA L.
Miss Clark

THE epoch making work of Aschheim and Zondek has definitely shown that hormonal secretions play a prominent rôle in pregnancy. These hormones are derived from the ovary and the pituitary gland and bear a direct relationship to ovulation, fecundation and menstruation. Recent investigation indicates that there are seven distinct hormonal effects from the pituitary gland and two from the ovary. The effects from the pituitary gland are

1. The anterior lobe.
 - a. An effect causing ripening of the graafian follicle with the production of folliculin and egg cell (1)
 - b. An effect which causes growth of the corpus luteum after ovulation (2)
 - c. An effect which in conjunction with the corpus luteum causes hypertrophy of the mammary glands (3 5 11 13 18 24)
2. The posterior lobe.
 - a. An effect causing uterus stimulation (12 13 18)
 - b. An effect causing expansion of melanophores (35)
 - c. An effect causing antidiuretic or water retention (32)
 - d. An effect causing increased blood pressure (9)

The effects from the ovary are

- a. Folliculin which causes hyperemia of the uterus and tubes in preparation for the egg cell (7)
 - b. Corpus luteum which produces further growth of uterus and hypertrophy of mammary glands (6 8)
- Ripening of the graafian follicles with the production of folliculin and ovum is brought about by an anterior pituitary hormone. Folliculin causes hyperemia of the uterus and tubes. When the follicle bursts the corpus luteum spurium is formed and this body in turn causes further growth of the uterus and hypertrophy of the mammary glands. If the egg cell is not fertilized the corpus luteum withers and dies and menstruation takes place. If the fertilized egg is implanted the corpus luteum spurium develops into the corpus luteum graviditatis, which maintains pregnancy and when it begins to wither the posterior lobe hormones re-assert causing rhythmic contractions of the uterus and labor. These reactions are shown by Figures 1 and 2 (13 14 15 30).
- Different scientists have shown that the life of the human egg cell is 1 day (18, 24, 34) and that of the sperm cell is 2 to 3 days (18 24, 36). Also that in a normal regularly menstruating woman with a cycle of 28 to 30 days

ovulation occurs between the fourteenth and sixteenth days (18, 24) and that 10 days are required for the passage of the egg cell through the fallopian tube (18)

Henle has definitely shown that spermatozoa are able to travel a distance of 1 centimeter in 3 minutes (37). That human spermatozoa may reach the fallopian tube in a very short time after being deposited in the female genitalia there can be no doubt as shown by the following case which we observed:

Mrs. B. M. age 25 1 para diagnosis dyspareunia prolapsed uterus. In this case the last coitus was 65 days previous. Examination of vaginal and cervical secretions did not show the presence of spermatozoa. Copulation was had at 8 a.m. 2 hours later at laparotomy examination of fallopian tubes revealed the presence of numerous spermatozoa.

If the duration of life of the egg and sperm cell is known as well as the rate of sperm cell motion the next question which confronts us is: When is the egg cell liberated?

Knaus by means of a manometer noted that there was increased uterine pressure following the injection of posterior lobe pituitrin due to uterine contractions and that when corpus luteum was present the uterus did not respond by contractions (36). In this manner he was able to determine the time of ovulation. This he found to be in the 28 day cycle of menstruation on the fourteenth to the sixteenth days before the next menstruation (18, 24). From these facts it is evident that in a 28 day cycle the corpus luteum spurium functions for about 14 days, when implantation of a fertilized egg occurs the corpus luteum spurium is changed to corpus luteum graviditatis or if fertilization and implantation do not occur it withers and dies and menstruation is brought about. On this view pregnancy is not a hit and miss affair but is regulated by the meeting of the egg and sperm cell before one or the other has withered and died (18, 36).

Ogino of Japan, studied this question by examining the coitus in relation to ovulation and noting its ability to fecundate. He arrived at the following conclusions:

1. For women regularly menstruating every 28 days the period of time the human sperm cell was able to impregnate the ovum was the 8 day period lying between the twelfth and the

nineteenth day before the next menstruation or in other words between the tenth and the seventeenth day after menstruation had started, other days being physiologically sterile.

2. If the cycle is longer or shorter than 28 days the period of conception is moved so many days ahead or behind.

3. For those women who do not have a greater variation in the menstrual cycle than 10 days a formula for the period of conception could be stated as follows:

Beginning of conception is 10 plus cycle of minimum days—28

End of conception period is 17 plus cycle of maximum days—28

4. In computing the period of conception of any woman 12 menstrual cycles should be known noting the maximum and minimum length of time of each. If the menstrual cycle should vary more than 10 days then the formula is still theoretically correct but of not much practical value (31).

Knaus of Austria working independently arrived at similar conclusions, but elaborated them more fully as follows:

1. For women with a regular menstrual cycle of 26 days, conception possibilities are limited to the time from the ninth to the thirteenth days inclusive.

2. For women with a regular menstrual cycle of 27 days, conception possibilities are limited to the time from the tenth to the fourteenth days inclusive.

3. For women with a regular menstrual cycle of 28 days, conception possibilities are limited to the time from the eleventh to the fifteenth days inclusive.

4. For women with a regular menstrual cycle of 30 days, conception possibilities are limited to the time from the thirteenth to the seventeenth days inclusive.

5. For women with a regular menstrual cycle of 34 days, conception possibilities are limited to the time from the seventeenth to the twenty first days inclusive.

6. For women with a regular menstrual cycle of 28 to 30 days, conception possibilities are limited to the time from the eleventh to the seventeenth days inclusive, with the maximum of same at the fourteenth to the sixteenth days.

Fig.

7. For women with a regular menstrual cycle of 26 to 30 days, conception possibilities are limited to the time from the ninth to the seventeenth days, inclusive of the menstrual cycle.

For menstrual cycles of other variations, the conception period may be computed in the same manner as stated above. These calculations being true only for normal healthy women with regular variations in the cycle as stated above (16, 19 to 29).

Ogino established the time of ovulation in an empirical manner during the course of laparotomies on women. He has a 5 day ovulation period in a constant menstrual cycle.

Knaus determined the time of ovulation by measuring the uterine contractions by means of a manometer. He has a 2 day ovulation period in a constant menstrual cycle. It seems to us that Knaus method is more definite and precise therefore we follow the doctrine of Knaus.

Based upon this initial research we decided to study this question by examining the coitus at various times to determine its ability to fecundate. Our material was chosen from 87 apparently normal couples including 8 nationalities and 735 copulations. Where pregnancy was thought to have occurred it was checked by the modified Aschheim-Zondek test on rabbits.

Our observations are as follows:

CASE 1. E. B., aged 36 years. Menstruation commenced at the age of 13, was of regular cycle, 28 to 30 days, duration 4 to 5 days. Patient was married at the age of 26 on the thirteenth day after previous menstruation, result pregnancy. For 5 years after birth of child, not desiring more children, various contraceptive methods as suppositories, douche powders, and pessaries were used. During the fifth year, while wearing a pessary she became pregnant and aborted at the second month. At this time she was informed by a friend to abstain from coitus between

Fig. 2

the tenth and twentieth day of her menstrual cycle. This she practiced successfully for 13 years without the use of any contraceptive measures whatever except accurately noting the dates on the calendar as well as duration of each cycle as the months went by. At the beginning of her fourteenth year of this procedure she was informed that she must not figure from the first day of menstruation but from the last. She accordingly changed her system. The next and only coitus occurred on the fourteenth day from the beginning of the last menstrual period. Result amenorrhea, of 3 months. On the third day after the second missed cycle the Aschheim-Zondek test revealed pregnancy. Ten days later by self-induced means, she aborted a 3 months fetus. In this case the cohabitation date lies within the period of conception for her.

CASE 2. F. E., aged 28 years. Menstruation began at the age of 14 years, was occurring every 26 to 28 days, duration 4 days. She was married at the age of 21 the date being about halfway between two menstruations. Result pregnancy. Following birth of child she developed a painful right ovary. Menstruation became profuse, 5 to 6 days in duration, varying from 26 to 34 days. She was advised by her physician that another pregnancy might result in an operation being necessary so she used various contraceptive measures for 6 years. At this time, feeling that her procedure was correct, she adopted a son. Later she was advised that contraceptives were injurious and unnecessary. If she would abstain from intercourse between the eleventh to the seventeenth days of menstrual cycle. The previous 4 periods were as follows: 26, 30, 28 and 33 days in duration. The only cohabitation during the month was on the nineteenth day after the beginning of the last menstruation. Result amenorrhea. The Aschheim-Zondek test proved the existence of pregnancy. This day lies within the dates of conception possibilities for her.

CASE 3. A. A. aged 25 years. Menstrual cycle varied from 29 to 33 days, duration 4 days. Last 4 menstruations were as follows: January 27, 1932; February 20, 1932; March 20, 1932; April 30, 1932. Only cohabitation on May 16, 1932, then amenorrhea. The Aschheim-Zondek test on June 22, 1932, proved the existence of pregnancy. The cohabita-

■ Menstruation ■ Period of conception. / < Maximum period of conception. □ Cohabitation.

tion date in this case falls within the conception period for this woman.

CASE 4 A. R. aged 26 years. Menstrual cycle was 27 to 33 days, duration, 4 days. The last 5 menstruations are as follows: January 2, 1932; February 3, 1932; March 1, 1932; April 3, 1932; and May 4, 1932. Only cohabitation was on May 18, 1932. The next menstruation due to occur during the first week in June failed to materialize by June 16 on which date the Aschheim Zondek test proved the existence of pregnancy. The cohabitation here is within the period of conception possibilities for this cycle.

CASE 5 A. N. aged 42 years, vi-para 3 abortions. Menstrual cycle was 30 to 31 days. Last two menstruations were as follows: January 10, 1932; and February 10, 1932. The only coitus was on February 25, 1932. The following day her husband left home to seek work in a distant state and was gone for 4 months. This woman did not menstruate during the next 3 months. Being in ill health and believing that she was entering upon the climacteric she consulted a physician. The Aschheim Zondek test proved pregnancy was the cause of amenorrhoea.

CASE 6 W. E. aged 22 years, regular 26 to 28 day cycle menstruation. Confinement on August 14, 1931. First menstruation postpartum was December 25, 1931. Next four as follows: January 22, 1932; February 17, 1932; March 16, 1932; and April 14, 1932. One coitus occurred on April 30, 1932. On May 14, 1932 Aschheim Zondek test was positive for pregnancy.

CASE 7 E. A., aged 21 years. Regular menstrual cycle 26 to 30 days. Last menstruation was on April 6, 1932. Cohabitation was on April 22, 1932. On June 11, 1932 Aschheim Zondek test was positive for pregnancy.

CASE 8 A. B., aged 40 years viii-para men- struation every 16 to 27 days duration 2 to 3 days. Last menstruation on August 10, 1931; cohabitation

on August 21, 1931. On September 18, 1931 Aschheim Zondek test was positive for pregnancy. In her case the conception date lies on the second day of the period of conception for her.

CASE 9 H. L. aged 35 years, no children regular menstrual cycle of 30 days duration 5 days. Last period was February 29, 1932, cohabitation March 13, 1932. Result pregnancy.

CASE 10 H. C., aged 21 years, on August 27, 1925 was confined. This woman believed that as long as she was nursing a child and did not menstruate that she could not become pregnant. Feeling secure in this belief no contraceptive measures were used. Eight months after her confinement, no menstruation having appeared as yet on October 12, 1926 she consulted a physician and pregnancy was diagnosed. She was again confined. In this case no menstruation occurred between the birth of the first child and the birth of the second child.

COHABITATIONS REGULATED BY TIME WHICH DID NOT RESULT IN PREGNANCY

CASE 1 A. F., aged 27 years i-para. This woman used the premenstrual and postmenstrual period of sterility for cohabitation. The details are shown in Table I.

In this case there were 48 cohabitations which did not result in pregnancy.

Eighty-seven cases consisting of 12 different menstrual cycles and 8 nationalities were studied for the period of physiological sterility. The details of this study are shown in Tables II and III.

Cohabitations before and after menstrua- tions total 725 and not a single cohabitation of these two groups resulted in pregnancy.

SUMMARY

The anterior lobe secretion motivates the ovary. The corpus luteum inhibits the posterior lobe secretion and maintains pregnancy. When the corpus luteum withers the oxytocic principle of the posterior lobe secretion asserts itself and labor is brought about. Fecundation is only possible when the sperm cell is properly timed to meet the egg cell.

CONCLUSIONS

1 Hormones play a major rôle in pregnancy.

2 The sperm and egg cells detached from their respective breeding places have a very limited time to live. For the egg cell it is not longer than 1 day. For the sperm cell it is 2 to 3 days.

3 Every normal regularly menstruating woman has a definite ovulation period.

4 Every normal regularly menstruating woman has a definite period of physiological sterility and a definite period of fertility in each cycle.

5 Cohabitation must be properly timed with ovulation if pregnancy is to result.

6 Pregnancy may be brought about or avoided at will by the observation of these two periods of time

THE INTERRELATIONSHIP BETWEEN OVARIAN FOLLICLE CYSTS HYPERPLASIA OF THE ENDOMETRIUM, AND FIBROMYOMATA

A POSSIBLE ETIOLOGY OF UTERINE FIBROIDS

J THORNWELL WITHERSTOON M.A. (OXON) M.D. NEW ORLEANS, LOUISIANA
Department of Gynecology School of Medicine, Tulane University

UTERINE fibroids, because they are the most common of all pelvic neoplasms should command the interest of every gynecologist. Various theories of their origin have been propounded, but no accepted explanation has yet been advanced and their true histogenesis will probably remain a mystery until the cause of neoplasms in general is discovered. However, recent additions to our knowledge concerning the ovarian and pituitary hormones now offer a definite approach to the origin and development of these benign tumors. Past research into the pelvic field has revealed the interrelationship of ovarian follicle cysts and hyperplasia of the endometrium and although in the evidence brought forth there exists numerous instances of the association of fibromyomata with these two conditions, the action of ovarian dysfunction on the myometrium has been little investigated or commented upon. I believe that the existence of an etiological relationship between hyperplasia of the endometrium, ovarian follicle cysts, and fibromyomata is highly probable and the results of my investigations have prompted the writing of this paper.

The histogenesis of fibroids is not definitely known, and lends itself to the explanations given to neoplasms in general: an origin from embryonic rests (Conheim) a product of connective metaplasia etc. McCallum is one of the few advocates of Virchow's uterine muscular origin theory and he contends that this belief is substantiated by the fact that myomata relax and soften during pregnancy and recover their hardness after confinement. Opitz suggests metaplasia of connective tissue since both uterine muscle and connective tissue originally develop from the same undifferentiated process of the mesenchyme continuation or repetition of this metaplastic process must occur to produce fibroids.

Rocager is of the opinion that fibroids arise from the walls of the blood vessels but this belief is not substantiated by Cullen. A relationship between uterine fibroids and the terminal branches of uterine arteries similar to that found between neuromata and the epineurium has been suggested other observers note an inflammatory cause von Recklinghausen considers wolffian remnants to be important in their origin, while still others believe that the development is to be found in the aberrant muellerian tissue. Ewing is of the opinion that the essential histogenetic factor is an embryonic disturbance in the structure of the uterus because of the remarkable degree of isolation of the many myomata their widespread occurrence over the body other than in the uterus and the presence in many cases of heterotopic inclusions, epithelial cartilaginous osseous, fatty and rhabdomyomatous, clearly point to an embryonic origin.

Numerous cases have been reported which seem to show that heredity may play some part in the etiology of fibroids although only 21 women in Lynch's series of 683 cases gave an indicative family history. The relative frequency of this type of tumor in negroes suggest the influence of race as a factor. In Charity Hospital New Orleans, where the annual admission of the white and colored patients is about equal, fibromyomata were noted 9 times as frequently in the colored patients as in the white. Bulloch describes this growth and other fibroid tendencies of the negro as a racial peculiarity, though there is a general impression extant that these growths were unknown among the primitive tribes. Why there should be any relationship between the development of fibroids and the advancing civilization of negro women is difficult to understand unless, as will be discussed in a subsequent paper ovarian dys-

function brought on by pelvic infection should play an etiological rôle. However scientific data are still wanting to confirm definitely that either heredity or race is the cause.

Sterility has long been noted as another factor in the etiology of fibroids since it is found to be three times as prevalent in association with fibroids as it is under normal conditions. Young and Williams (Lockyer) note 10.5 per cent sterility in all women who have attained the age of 38 while in a large series of cases of fibroids Cullen Phillips Olhausen and Lynch found 30 to 33 per cent sterility in the married woman. It is an accepted fact that fibroids occur most frequently in virgins and in absolutely or relatively sterile women. One child sterility is frequently observed and in Miller's 150 cases of fibroids 50 per cent of the fertile colored women had only 1 child. Lynch and Cullen offer as an explanation of this observation the fact that uterine muscle is primarily designed to respond to pregnancy in all of its various functions and manifestations and should no pregnancy intervene this organ responds to a less influential stimulus and hypertrophies in an abnormal fashion resulting in the development of fibroids. This theory however does not offer any explanation of the development of fibroids in a parous woman, nor does it explain their stimulation to rapid growth when associated with pregnancy. Fibroids because of their size and pressure and the high incidence of associated infection, often cause mechanical sterility. Both sterility and fibromyomata are prone to develop in the infantile type of uterus as well as from displacements and other uterine defects which often enhance the early termination of the pregnancy by abortion. The essential problem is whether sterility is the cause of fibroids or fibroids the cause of sterility.

In view of the fact that the occurrence of fibroids is generally noted during the child bearing years of woman menstruation should play an important part in their etiology. On this hypothesis Sampson offers as an explanation local hyperplasia of the uterine muscle cells caused by the stimulus of men-

strual blood which has acquired access to the myometrium by retrograde flow through the venous sinuses of the endometrium. As proof, the author cites the fact that smooth muscle tissue in contact with heterotopic endometrial tissue, often shows a tendency to grow. The absence of fibroids in the tubes and in the cervix is explained by lack of menstruation in these parts. Sampson suggests that the cause of the greater frequency of fibroids in the human female over that in the lower animals is due to the monthly periods in woman since the animal cycle is not true menstruation. Moench points out however that menstruation does occur in the ape and that fibroids are relatively unknown in this animal.

There is a general clinical impression that glandular dysfunction is associated with fibroids. Polak's observation of unbalanced glandular patients lead him to believe that the hyperpituitary type of woman, who begins her menstrual life with an anteverted anteфлекted uterus, and a relative large uterine body is prone to develop fibroids. He has followed 100 or more women over a 10 to 15 year period and has "watched them grow fibroids." Fibroids often develop in the subthyroid and the subpituitary types with anteфлекted retroverted uteri, and with clinical symptoms of glandular hypoplasia, primary dysmenorrhea and sterility. On the other hand, women of perfect endocrine balance seldom grow fibroids even though pregnancy is a frequent occurrence, with the uterus passing through alternate periods of hypertrophy and involution. In reviewing 683 cases of fibroids, Lynch observed thyroid involvement, adenoma, hyperthyroidism or simple goiter singularly or in some combination, in 106 patients (15.5 per cent). In 394 cases of large fibroids the abnormality of the thyroid was involved in 77 patients (19.5 per cent).

Ovarian activity has generally been considered a factor in fibroid development because of its occurrence during woman's functional years, and while this consideration has been based only on clinical observations and general impressions its existence evidences a trend of thought along the line of ovarian hormone influence on the uterus. Schroeder and R. Meyer, in Germany and

Novak, Fluhmann and Graves in this country have brought forth convincing evidence to prove the relationship between ovarian follicle hormone and hyperplasia of the endometrium. This pathological condition manifests itself as irregular uterine bleeding which is most frequently noted clinically at the two extremes of woman's functional years, and histologically is described as containing a characteristic lack of uniformity of the glandular elements embedded in a varying amount of densely packed stromal proliferation, the so-called Swiss cheese pattern. Because of its microscopic resemblance to hypertrophy of the basal layer of the endometrium the hypothesis is logical that its structure results from overgrowth of this layer at the expense of the superficial layers whose growth is governed by the hormone of the corpus luteum.

Schroeder had an opportunity of examining the uterus and both ovaries in 62 cases of hyperplasia of the endometrium. In 53 instances the ovaries contained 1 or more small cysts lined with well preserved granulosa and theca layers in a few instances the ovum was demonstrated in the granulosa cells. In the 9 remaining cases the follicles were undergoing degeneration and one early corpus luteum was seen, but was thought to have been ruptured a few days previously by bimanual examination. From these observations Schroeder proposed the theory of 'pathological persistence of a ripening follicle' as the cause of hyperplasia of the endometrium. He contends that the ovum does not die and the follicle unruptured, continues to function resulting in excess secretion of the follicle hormone. R. Meyer substantiated the evidence of the absence of the corpus luteum formation in hyperplasia but he noted large cysts of the ovaries caused from apparent follicle atresia in addition to the many normal granulosa cell cysts. The walls of the larger cysts presented an unusual hypertrophy of the theca cells. Theorizing from these observations, Meyer advanced the idea that the ovum dies prematurely due to some unknown inherent weakness and in consequence the follicle does not reach complete maturity nor does it rupture but undergoes atresia at an earlier period. Immediately another

ripening follicle appears and the process is repeated thus maintaining continuous ovarian follicle stimulation to the endometrium. Even though the explanations of Schroeder and Meyer of the methods of production of the follicular hormone differ they completely agree that continuous stimulation by it in the absence of corpus luteum influence is the cause of hyperplasia of the endometrium.

In a smaller series of cases Fluhmann, Graves, and Novak generally support this hypothesis as the cause of endometrial hyperplasia as attested by the following facts: (1) It is observed only during woman's functional years (2) it occurs at the two extremes of woman's menstrual life when the ovarian cycle tends not to follow its normal rhythm, since it is just beginning or ending (3) there is no evidence of inflammatory origin since it occurs in very young girls (4) the bleeding resulting from it is checked by removing the ovaries and destroying ovarian function by X-ray (5) curettage gives only temporary relief suggesting that the underlying cause has not been reached (6) the presence of follicle cysts is constantly found and excess follicle hormone content is noted in the blood at such periods (7) estrin has been proved experimentally to be a growth hormone to endometrial glands and stroma and hyperplasia presents similar histological characteristics (8) it found after the menopause from granulosa cell tumors which give rise to excess estrin or hyperestrinism (Graves) in the blood (9) the absence of corpora lutea precludes the formation of progesterin (10) and the lack of progesterin the corpus luteum hormone is confirmed by the absence of endometrial secretory changes, normally produced by this hormone.

Since the discovery of the 'motor control' of the anterior pituitary gland over the ovarian function Novak and Burch have suggested the anterior hypophysis acting through the ovary as being the fundamental etiological factor of hyperplasia of the endometrium. According to Novak the interrelationship of the anterior hypophysis is chiefly responsible for the alternating phases of the long continued amenorrhea and persistent bleeding seen in the familiar type of

adiposogenital dystrophy. The participation of this gland as an etiological factor is further suggested by the cases of functional bleeding occurring after full term pregnancies or miscarriages since it is well known that the anterior pituitary gland undergoes marked hypertrophy during gestation. Novak has obtained splendid clinical results from the treatment of functional bleeding by the administration of anterior pituitary hormone, while Burch has demonstrated experimentally that there is a definite cyclic variation in the capacity of the anterior lobe to produce ovulation.

From the above evidence it seems legitimate to conclude that hyperplasia of the endometrium is the result of the unopposed and continued action of the ovarian follicle hormone in the absence of the corpus luteum influence. If this be true the reverse ought to hold, namely, when endometrial hyperplasia is found in curettings the diagnosis of ovarian follicle cysts can be assumed. Since the uterus as a whole is involved in the reproductive process it seems logical to deduce that the action of estrin is not limited solely to the endometrium but that the myometrium is also involved, especially if there be pathological stimulation to this myometrial tissue at the same time that the endometrium is abnormally stimulated to hyperplastic formation.

Novak has observed in evidence presented but unmentioned upon the association of ovarian follicle cysts, hyperplasia of the endometrium, and fibromyomatous changes in the myometrium. In 32 uteri with hyperplastic characteristics of the endometrium he found myomatous involvement of the myometrium in 23 cases (71.8 per cent). In 15 cases the myomata were alone, 5 were combined with adenomyomata and in 3 cases the latter growth alone was present. Turco comments upon the cystic degeneration of the ovaries in 11 cases of fibroids, but concludes that it is difficult to tell whether degeneration of the ovaries was the result or cause of the fibromyomata. Graves in 237 cases of hyperplasia treated with radium, noted fibroids clinically in 50 per cent. In 25 cases of fibroids in which hysterectomy and bilateral

oophorectomy were done, he found 11 cases of hyperplasia. In the same communication this author discussed uterine bleeding with and without fibroid association; his conclusion was that abnormal uterine bleeding associated with fibroids is identical in etiology and character with the so-called idiopathic or functional uterine hemorrhage characterized by the "Swiss cheese pattern" of the endometrium except in cases of pedunculated degenerating and submucous fibroids, and exposed adenomyomatous growths.

Since the rate of growth of fibromyomata is not exceedingly rapid except in pregnancy, malignancy, and possibly in youth it would seem legitimate to assume that if these growths are the results of the unopposed estrin stimulation of the myometrium their appearance would be slower than the hyperplastic endometrial changes. Hence it might be concluded that the unopposed action of estrin on the uterus results (1) in immediate endometrial changes, characterized by hyperplasia and (2) in more latent myometrial pathology in the nature of fibromyomatous growths.

With this hypothesis as a basis an analysis was made of 26 cases of hyperplasia of the endometrium in which operation was done and diagnosis as such made, and in which a second operation was performed for fibromyomata after an approximate interval of 4 years and 4 months. In addition 124 cases of fibromyomata which were diagnosed microscopically, are offered with the associated ovarian and endometrial findings as presenting added evidence in support of a cause and effect relationship and suggesting a possible factor in the development of uterine fibroids.

I. In the first group of 26 cases of hyperplasia of the endometrium a curettage was performed, and in no instance was a fibromyoma determined clinically or grossly at the time of this operation even though the abdomen was opened in 13 cases (50 per cent). After varying intervals all 26 patients were operated upon again because of uterine fibroids, and the findings of the ovaries, endometrium, and myometrium are offered (Table I).

TABLE 1.—ANALYSIS OF TWENTY SIX CASES

	Cases	Condition of myometrium	Cases
Age in years		Fibromyomatous	26
30 to 39	4	Hyperplastic	6
30 to 34	10	Fibrotic	5
35 to 39	9	Malignant degeneration	1
40 to 44	8	Adenomyomatous	1
45 to 49	1	Normal	1

Shortest.	1 year 2 months		
Type of second operation			
Hysterectomy	26		
Bilateral salpingo-oophorectomy	13		
Removal of all ovarian tissue	8		
Unilateral salpingo-oophorectomy	8		

The age limits were well within woman's functional years 30 to 39 years accounting for 73 per cent of all patients, the average being 35 plus years. The symptoms between the first and second operations offer an interesting comparison the outstanding feature of which is an increase of complaints. Menorrhagia and dysmenorrhoea were more frequent after the first operation while metrorrhagia decreased. An abdominal mass appeared in 5 instances, while nervousness in the form of irritability became a complaint in a similar number of cases. Radium caused a temporary amenorrhoea in 2 cases for 3 and 6 months, respectively but was non beneficial in 4 cases. Pregnancy occurred in 2 women after the initial curettage. The interval between the first and second operation averaged $4\frac{1}{3}$ years, with limits of $1\frac{1}{6}$ years to $13\frac{1}{6}$ years. Twenty-nine curettages were performed including 2 on 1 patient and 3 on another. The abdomen was opened at the first operation in 13 cases (50 per cent) and in 5 patients the ovaries were diagnosed microscopically as containing follicle cysts. In an equal number of cases the

operator noted the same condition grossly and punctured the multiple cysts with a needle. No mention of the operative condition of the ovaries could be found in the operative notes of 3 patients whose ovaries were not disturbed. The amount of curettements was described in 18 instances but since many different doctors performed the 29 curettings the description of the curettements naturally varies with the individual operator.

The uterus was removed in every instance at the second operation. Bilateral salpingo-oophorectomy was performed in 13 cases while all the remaining ovarian tissue was excised in 5, a total of 69.2 per cent. One ovary was left *in situ* in 8 cases. Multiple fibroids were observed in every case and in general the longer the interval between the operations the larger the fibroids. The myometrium was normal in 11 cases (42.3 per cent) even though fibroids were present in the walls. Hypertrophy of the myometrium was noted in 6 instances (23.3 per cent) and fibrosis i.e. increased connective tissue in 5 cases (19.2 per cent). The endometrium was either hyperplastic or polypoid in 24 cases (92.3 per cent), the premenstrual pregestational stage was observed in 2 instances associated in each case with a developing corpus luteum and interestingly enough it occurred in the 2 patients who had borne children after the initial curettage for hyperplasia of the endometrium. The fibroid tumors in these 2 cases were multiple but small.

Unless both ovaries or the total ovarian tissue are studied in their entirety it is unwise to draw conclusions concerning the presence or absence of the corpus luteum since its absence is so importantly related to hyperplasia of the endometrium. In 18 cases (69.2 per cent) both ovaries or the total remaining ovarian tissue were studied. In 8 cases (30.8 per cent), in which only 1 ovary was available for study 2 corpora lutea were observed in the developmental stage, and in each case the secretory phase of the endometrial cycle was associated. In 24 cases (92.3 per cent) no mature corpus luteum could be found, while old degenerating luteal cysts were observed in 5 instances. Follicle cysts of the ovaries were

present in all 26 cases including those in which the corpora lutea were found. Any explanation I can offer of the presence of follicle cysts in association with a developing corpus luteum must be in the nature of an hypothesis. That hyperplasia of the endometrium is not always a permanent condition has been observed frequently in young girls many of whom subsequently bear children, yet its persistence is noted as long as follicle cysts are found in the ovary. However when menstruation begins to return to normal ovulation with the usual subsequent corpus luteum formation must occur and at such periods the change from abnormal functional bleeding over to normal menstruation the existence of both follicle cysts and corpus luteum might be observed.

In 25 cases (96.1 per cent) salpingitis or adhesions from previous operations or endometrial transplants were noted involving the ovaries. The importance of this finding as a possible etiological factor in follicle cyst formation with subsequent ovarian dysfunction is not to be minimized. The endometrial transplants, mainly to the ovaries (71.4 per cent) were noted in 7 cases (27 per cent). The rather high percentage of this condition associated with hyperplasia of the endometrium and fibroids as compared with other gynecological conditions in general is noted as a possible etiological factor of endometriosis.

These 26 cases of hyperplasia of the endometrium on which a second operation was performed on an average of $4\frac{1}{2}$ years later for myomatous growths of the uterus are convincing evidence of a cause and effect relationship of the prolonged and unopposed action of estrin on the myometrium and the development of fibromyomata.

II. A second group of 83 patients on whom hysterectomy was performed for fibroids also supports the hypothesis of the existence of an interrelationship between ovarian follicle cysts, hyperplasia of the endometrium, and myomatous growths of the myometrium (Table II).

Even though both ovaries or the total ovarian tissue were available for study in only 50 per cent of the cases follicle cysts were found in every instance, while no mature

corpus luteum was noted. Likewise, hyperplasia of the endometrium and fibroids of the

uterus were noted in every case. Again salpingitis and chronic inflammatory adhesions were found in 97.6 per cent of the patients while endometrial transplants were observed in 25 cases (30 per cent). While the 97.6 per cent of pelvic inflammatory disease offers a possible explanation for the follicle cyst formation and the subsequent ovarian dysfunction because of the disturbed blood supply to this organ the high percentage of endometriosis again suggests a possible etiological source from hyperplasia of the endometrium.

III The findings in a third group of 41 cases of fibroids and hyperplasia of the endometrium although the evidence is indirect since the ovaries were not available for study microscopically but were only commented upon grossly at the time of operation likewise support the hypothesis of a cause and effect relationship between hyperplasia of the endometrium, ovarian follicle cysts, and fibromyomata. However as noted previously if follicle cyst formation resulting in hyperestrin stimulation is accepted as the cause of hyperplasia of the endometrium the logical inference should follow that the findings of characteristic hyperplasia microscopically warrants the diagnosis of ovarian follicle cysts. Hysterectomy was performed in every case for multiple fibroids (Table III).

Hyperplasia of the endometrium was found in every instance. Likewise the operator commented upon the small ovarian cysts in each case. The operative observation of salpingitis

DEDUCTIONS

The evidence advanced by Schroeder Meyer Graves, Novak and Fluhmann is certainly sufficient to warrant the acceptance of a cause and effect relationship between hyperestrin stimulation of the ovary and hyperplasia of the endometrium. Since the ovary reacts upon the uterus in its entirety and not just upon the endometrium some change in the myometrium should manifest itself from the unopposed action of estrin. One hundred and fifty cases of fibroids associated with ovarian follicle cyst formation and necessarily hyperestrinism are offered to suggest a resulting fibromyomatous change in the myometrium, if the stimulation is prolonged sufficiently. If this be true that hyperestrinism is the ignition so to speak of the fibromyoma, it does not follow that the hormonal stimulation has to persist after the growth is once present as proved frequently in our clinical experience in observing the combination of myomata and pregnancy. In such a condition we know the morphology of the endometrium is decidua and not the hyperplastic 'Swiss cheese pattern.' Whether the ovary is primarily responsible for the hyperestrin production or not is an un-

Fig. 2 Typical microscopic hyperplasia of the endometrium

settled question but in view of the newer knowledge of the motor hormone control by the anterior hypophysis it would seem more probable that the latter plays the important rôle especially since according to Novak the administration of its hormone can produce beneficial clinical results in functional uterine bleeding. Moreover it is contrary to the law of nature which maintains an external control over all organs or organisms that pass through a definite cyclic rhythm, that such an important organ as the ovary should maintain an intrinsic and automatic control over itself in having a beginning continuance and ending as shown by woman in her functional years. Yet it does not follow that if the ovarian function or rhythm is disturbed that the anterior hypophysis is always the cause. Any structure involved in the mechanism of its function might be at fault especially the blood supply as evidenced by the frequency of cystic degeneration of the ovary from disturbed nutrition after hysterectomy or salpinxgectomy.

Moench is of the opinion that the follicle cyst formation of the ovary is due to ovarian congestion and increased blood supply to these parts causing an increased number of follicles to ripen and not to an inflammatory process as formerly believed. This observer explains the presence of functional bleeding around the menopause as due to increased

Fig. 3. Multiple follicle cysts of the ovary

pelvic congestion since women are heavier less active more constipated, and have perhaps lessened muscular tone. Favoring such an hypothesis Polak and Mazzola, in experimental torsion of the vessels around the uterus parametrium and contiguous tissues, found marked hyperplasia and hypertrophy of all uterine layers. In addition there was a marked increase in the size and number of the blood vessels also the connective tissue ratio of the entire organ was greatly increased.

In accepting ovarian and uterine congestion as a cause of follicle cyst formation of the ovaries and myomatous growths of the myometrium, many findings are left unexplained, particularly the high incidence of fibroids in the negro race, the absence of fibroids during pregnancy when the uterus is most vascular and the non-development of fibroids in acute pelvic diseases and puerperal sepsis when the vascularity of the uterus and adjacent structures is highly increased.

I am inclined to believe that the cause of formation of follicle cysts of the ovary is not to be found in a passive congested state of these organs and adjacent tissues, but as previously discussed, in the disturbance of the blood supply to these parts. The most frequent occurrence of this follicle cystic change in the ovary is at the two extremes of woman's reproductive life at puberty the ovaries and

uterus undergo development in size and function with a natural increase in the blood supply. If this supply cannot keep pace, as it were with the anatomical and functional demands made upon it, naturally the organs must suffer from the insufficient blood supply and the results are possibly manifested in the ovaries by follicle cystic changes. At the other extreme the menopause, the reverse process occurs. The ovary has been passing through rhythmic monthly cycles, requiring variations of the blood supply to it and supplying the demands made upon it by the organism as a whole as the menopause approaches, the ovarian blood supply is curtailed as is seen in all other pelvic organs. If the blood supply becomes disturbed too quickly might not follicle cystic formation result before the natural senile inactivity of the ovary takes place?

The ovaries of negro women are being studied in an attempt to show that disturbed ovarian blood supply resulting from the high incidence of chronic pelvic inflammatory disease in this race, is the source of follicle cystic changes in the ovaries the findings will be presented in another communication. For the present I need only quote Miller who in 150 cases of fibroids in negroes, found tubo-ovarian disease in 93 per cent of the cases, and cystic degeneration of the ovaries in 80 per cent while Alsbrook, in 100 cases of fibroids in negroes, noted salpingitis in 99.1 per cent. In the present survey both chronic infections and adhesions were observed in over 95 per cent of the cases in addition to the follicle cyst formation and the ovarian stroma was considered atrophic, degenerative and fibrotic in an equally high percentage.

If as suggested by this paper there be a cause and effect relationship between ovarian follicle cyst formation resulting in immediate endometrial hyperplasia, and later in fibromyomatous growths of the myometrium the work of Novak and Hurd offers great therapeutic encouragement as a prophylaxis against fibroid formation. These observers have obtained cessation of bleeding in 44 of 51 cases of functional uterine hemorrhage by the administration of the anterior pituitary hormone and the restoration of the normal

menstrual rhythm seems apparent. If further study proves the result to be permanent it would seem legitimate to predict a decrease in the incidence of fibromyomatous growths in the white race through the prophylactic treatment of ovarian hyperestrinism with the luteinizing factor of the anterior hypophysis.

SUMMARY

1. The various theories pertaining to the histogenesis and etiology of fibromyomata of the uterus are discussed.

2. Evidence is offered to show that the unopposed action of estrin in the absence of the corpus luteum influence is the cause of hyperplasia of the endometrium.

3. An hypothesis is advanced to suggest that the unopposed action of estrin on the myometrium if prolonged sufficiently would result in fibromyomatous growths.

4. Twenty six cases of hyperplasia of the endometrium in which operation was done and diagnosis as such made from microscopic study and in which a second operation was performed for fibromyomata after an approximate interval of 4 years and 4 months are analyzed.

5. One hundred and twenty four cases of fibromyomata, diagnosed microscopically are offered with their associated ovarian and endometrial findings as presenting added evidence in support of a cause and effect relationship between ovarian follicle cystic formation hyperplasia of the endometrium and fibromyomata of the uterus.

6. An hypothetical conclusion is advanced that the unopposed action of estrin on the

uterus results (1) in immediate endometrial changes characterized by hyperplasia and (2) in more latent myometrial pathology in the nature of fibromyomatous growths.

CLINICAL SURGERY

FROM DEPARTMENTS OF ANATOMY AND SURGERY UNIVERSITY OF NEBRASKA

REPAIR OF HIGH LACERATIONS OF THE RECTUM WITH COMPLETE INCONTINENCE

ANATOMICAL PRINCIPLES AND OPERATIVE TECHNIQUE

R. RUSSELL BEST, M.D., F.A.C.S., OMAHA, NEBRASKA

IT is interesting to note the accomplishments and successes that follow the varied techniques in the treatment of lesions amenable to surgical therapeutics. In most instances the principles are the same, the variation being in some of the details. I believe that when there is a choice, the simpler technique should be elected, provided reasoning and experience have proved that the more complicated procedure is unnecessary.

In a review of the literature on the technique used in repair of high lacerations of the rectum with complete incontinence, associated with third degree lacerations of the pelvic floor, the methods of fourteen different operators were consulted. Eleven of these including Orr, Ristine, Noble, Tait, Ward, Emmet, Marcy, Goldspohn, Farrar, Kelly, and Crossen used silver wire silkworm gut, or kangaroo retention sutures; only three operators, Titus, Watkins, and Clark repaired the perineum and sphincter and without the use of retention sutures. Despite the variance in this one principle of the technique, all of these authors claim equally good results. The first group who employ retention sutures usually of an unabsorbable nature focus the disadvantage of the necessary removal of the sutures some days later. Also retention sutures cause more discomfort to the patient.

During the last 3 years I have performed the operation six times by the simpler technique of avoiding retention sutures and all have been successful, including one operation which was carried out 12 years after the primary injury. Although very few authors report this operation without the use of retention sutures, I believe if the principles for attempting an anatomical restoration are followed with close adherence to careful operative technique and postoperative care, success is assured without the use of painful unabsorbable retention sutures which require removal.

The anatomy of the pelvic floor and its relation to the rectum and vagina have been well taught by Tandler, Halban, Edouard, Martin, Testut, and Jacob (Figs. 1 and 2). The principles of pelvic floor repair have been sponsored by Emmet, Tait, Marcy, Watkins, and Ward. The principles and methods of repair for high lacerations of the rectum were first introduced by J. Collins Warren in 1875. Ristine popularized this operation. Kelly initiated the individual suture of the sphincter and muscle. Of late Farrar has emphasized the use of this operation in extreme high lacerations of the rectum by dissection of the flap high on the posterior wall of the vagina just below the cervix.

The technique that is used in the repair of my cases is of the simpler type in that no retention sutures are used. Over a period of 3 days prior to the operation, the vagina and rectum are well prepared by twice daily irrigations of 1,000 potassium permanganate. On the day previous to operation the patient is on a liquid diet and on the evening before operation is given a normal saline enema repeated until it returns clear. When the patient is brought to the operating room, both the rectum and vagina are thoroughly irrigated with a quart of 1 per cent lysol solution. During this stage of the operation I prefer to wear two pairs of rubber gloves so that if it becomes necessary the index finger of the left hand may be inserted into the rectum to act as a guide. The flap is outlined as indicated in Figure 3, and if the tear reaches quite high on the rectal wall there should be no hesitation in extending it up to the level of the cervix. As indicated in the small diagram, care must be taken that the distance from *a* to *b* is slightly greater than from *b* to *c*; otherwise, the flap will be of insufficient length, and it is the vaginal surface of this flap which, when turned down, becomes the anterior surface of the lower rectum and anus. Care must also be

Fig. 1. Pelvic outlet exposed with removal of the skin, labia, subcutaneous fascia, superficial perineal fascia and contents of ischioanal fossae. *A* Ischioanocavernosus, *B* bulbocavernosus, *C* superficial transverse perineal, *D* levator, *E* gluteus maximus, *F* sphincter ani, *G* urogenital diaphragm. *H* Bartholin's gland. (The superficial stratum *I*, *B* and *C* has been removed on the right side, thus exposing the middle stratum, urogenital diaphragm. The levator ani is considered the inner stratum.)

Fig. 2. There has been a complete laceration destroying the perineal body with the resulting separation of the bulbocavernosus muscle, the transverse perineal muscles, the sphincter ani muscle and the levator ani muscle. The vagina and rectum are now one cavity. *A* bulbocavernosus, *B* transverse perineal, *C* sphincter ani, *D* urogenital diaphragm, *E*, levator ani.

exercised not to buttonhole the rectum. The flap in the anal margin must extend lateral to the dimpled or palpable ends of the sphincter ani muscle. When it has been turned down as shown in Figure 4 the extra pair of gloves may be removed and at this time the operative area and the rectum should again be irrigated with 1 per cent lysol solution. From now on, rectal contamination is not probable.

After this flap has been turned down by either blunt or sharp dissection the levator ani muscles are found, particular care being taken to pick up these muscles far back from the introitus because the firmer and more accurate approximation that is made of the levator ani muscles and fascias around the rectum, the more they act as accessory muscles in sphincter control. Although simple interrupted sutures of No. 2 chromic catgut may be used, I prefer to use interrupted No. 2 chromic catgut figure-of-eight sutures to approximate the edges of the levator ani muscle. Usually about three sutures are necessary. This builds up a very good muscular wall separating the vagina and rectum and helps cover over the flap of vaginal mucous membrane which has been turned down to form the anterior wall of the rectum. As shown in Figure 5 several interrupted No. 1 chromic catgut sutures are then used to close the upper end

of the vaginal exposed area by bringing together the edges of the mucous membrane and the margins of the urogenital diaphragm. This bringing together of the levator ani muscles holds the rectum somewhat forward and serves as a splint to the perineum for the repair of the sphincter muscle and the transverse perineal muscles. Both the superficial and deep transverse perineal muscles have been lacerated in the complete tear and approximation of these further strengthens the former central point of the perineum. Sometimes there is considerable difficulty in locating the ends of the transverse perineal muscles. These muscles just mentioned are usually sutured with No. 1 chromic catgut figure-of-eight sutures, both ends being brought to the central point anterior to the rectum. Careful search is then made for the ends of the sphincter ani. When the ends have been located care must be taken not to isolate them too freely or more retraction is likely to take place and with fascia removed the sutures to be placed have less likelihood of holding. This surrounding scarred and fibrous tissue tends to splint the muscle and hold it in fairly good position. The ends are brought together by a No. 0 chromic catgut figure-of-eight suture and this suture in turn picks up a bit of muscular and fascial tissue in the newly made central point of the perineum (Fig. 6). An interrupted No. 1 chromic catgut suture closes Colles' fascia and brings the skin margins together

Fig. 3

Fig. 4

Fig. 5

Fig. 6

Fig. 7

Fig. 3. Large cut. Outline of incision to be made into the mucous membrane of the vagina. Dissection is carried downward from point A. The margin of this flap must be outside of points B which usually indicate by small depressions or by palpation the ends of the lacerated sphincter and muscles. Small cut. The length of the flap from a to b which is the top of the laceration, must be as great or greater than, the distance from b to c. The mucosa of this flap when turned down faces the rectum and anus. Points d must be outside of the sphincter ends, *sp*.

Fig. 4. The flap B has been turned down and the levator and muscles, exposed. Interrupted No. 2 chromic catgut sutures have been placed. This bridges over with

muscle and fascia the defect present between the anus and rectum.

Fig. 5. The levator and sutures have been tied. One suture in the mucosa has been tied and one is in place. The suture marked C is interrupted chromic catgut and must grasp the mucous membrane, and the turn edge of the urogenital diaphragm.

Fig. 6. A Suture grasping the transverse perineal muscles; B suture grasping the ends of the sphincter and muscle.

Fig. 7. The mucosa and fascia have been closed with interrupted chromic sutures. A Final puckering suture through flap and skin edges.

subcutaneously. A small purse string suture of No. 0 chromic catgut takes up the excess tissue of the flap and slightly puckers it around the anterior margin of the anus (Fig 7). The operation is then completed by injecting 1 to 2 ounces of sterile vaseline into the rectum. This tends to act as a mold and as a protective dressing for the lower rectum and anus. However its principal function is to serve as an effective lubricant at the time of the first bowel evacuation after operation.

The after-care of these patients is most important. The perineum must be kept clean by repeated external douches of 1:5000 potassium permanganate solution after each urination or bowel movement, in any event the douches should be given twice a day. The thighs must be kept together. The patient should be on a liquid diet without milk for 5 days and then on a soft diet for 5 days. Bowel evacuation is stimulated on the fifth day by giving citrate of magnesia. At no time are enemas given and after the fifth day constipation is prevented by giving petrolagar twice daily and a small dose of citrate of magnesia every other day if necessary. About the tenth day rectal examination is made at first introducing only the little finger. This should be repeated every 2 or 3 days in order to prevent any stricture formation.

ARRHENOBLASTOMA OF THE OVARY¹

J. M. TAYLOR, M.D. S. J. WOLFERMANN, M.D. AND FRED KROCK, M.D. FORT SMITH, ARKANSAS

We are indebted to Meyer for calling our attention to the rather novel conception that tumors have function much as any normal organ. This fact is ordinarily overlooked, although the cachexia associated with malignant disease has been noted for centuries. The best example of neoplastic function occurs in the ovary which is the site of certain unusual tumors, notably the granulosa cell carcinomata whose secretions produce an exaggerated femininity as evidenced by precocity of sexual development in the young subject and rejuvenation in the old and some of the arrhenoblastomata whose hormones not only defeminize, but masculinize their hosts. The term arrhenoblastoma (meaning to make like a male) as proposed by Meyer to cover this interesting group of masculinizing tumors of the ovary numbering 26 in the literature today is restricted to those tumors which show male characteristics histologically as well as clinically and further excludes those cases of ovario-testis or true hermaphroditism.

This case is being reported not only as an example of this extremely rare condition, but in order to illustrate the powerful influence exerted by sex hormones, both normal and abnormal, upon the development of the secondary sexual characteristics of the body.

REPORT OF CASE

One of us (J. M. T.) was called to see Miss M. E., Case N. 32-32, a white school girl, 18 years old, who entered St. Edward Mercy Hospital January 30, 1932, complaining of severe abdominal pain, cough, fever and pain in the chest. The family history was irrelevant except that both parents were born in Germany.

The past history was negative except for the extremely interesting story concerning the reproductive system. She began menstruating at the age of 3 years, with a regular interval of 25 days, moderate flow without pain, lasting 4 to 6 days. At the age of 14 years the menstrual periods suddenly ceased and patient has not menstruated since that time. At the age of 6 years she noticed the development of excessive hair on the face and over the body which was progressive to the extent that it was necessary to shave the face with increasing frequency. A change was also noted at this time in the voice, it at first becoming coarse, then developing a contralto quality and reaching the present stage of a very definite baritone.

The onset of the present illness occurred about 1 month previously when she noted pain in the lower part of the abdomen with progressive enlargement. A few days before admission she developed a cough, followed by pain in the chest, fever and the expectoration of blood tinged sputum.

Physical examination at the time of admission showed a very sick young white girl who was mentally alert, clear

and co-operative. The appearance of the face with bushy eye-brows and marked beard, was very striking, and suggested that of a young man. The hair of the head, while short, was rather profuse. The temperature was 104 degrees orally, the pulse rate 158, and the respiratory rate 58. The blood pressure was 105/60. There seemed to be an excessive pallor to the skin and mucous membranes. The patient was coughing incessantly and at times expectorating blood tinged sputum. Dyspnea, approaching cyanosis, with suppressed breath sounds, was found over the entire posterior aspect of the left lung, with numerous coarse rales over the upper portion. The right lung was clear. The breasts were flat and atrophic. The nipples were coarse, pigmented, and a circle of long hair was present in the areola. No abnormalities were noted about the heart. There was a marked generalized hypertrichosis, especially noticeable in the axillae, forearms, inside the thighs, and around the perineum. The distribution of the pubic hair was of the masculine type with a heavy ridge in the midline extending up to and around the umbilicus. The abdomen was enlarged in the lower half due to an abdominal tumor the size of a 6 months' uterine pregnancy and extending down into the pelvis. Tenderness in the left lower quadrant was so exquisite that the patient could hardly bear the weight of the bed covers on her abdomen. On vaginal examination the clitoris was found to be hypertrophied to three times normal size, with well developed prepuce, the hymen absent, and the vaginal canal contracted so as to admit one finger with difficulty. The cervix was small, soft, and the uterus could not be outlined. Motion was not communicated to the cervix by moving the tumor from above the symphysis. The mass could be felt partially distending the cul-de-sac and lateral fornices.

A markedly flat masculine type of pelvis with masculine type of skeleton was shown by the following measurements of pelvis and shoulders: Pelvis—spines 23.5 centimeters, crests 24 centimeters, trochanters 26 centimeters, external conjugate 15 centimeters, and bichiasmic tuberosities 8 centimeters, shoulders—36 centimeters.

Clinical laboratory studies gave the following results. Blood examination showed erythrocytes 5,000,000; hemoglobin 60 per cent, leucocytes 7,000 differential—Schilling count—juvenile cells, 21; staff cells, 17; segmented cells, 68; lymphocytes, 16; eosinophiles 0. Shift to the left so nuclear index 3½ malaria negative Wassermann negative.

Urinalysis, no 8 acid trace albumin, no sugar few unclumped white cells.

X ray report by Doctor W. R. Brookshier, Jr., abdomen, large dense abdominal and pelvic tumor head, normal sella turcica, chest, massive pleural effusion, left side.

Patient continued to vomit frequently and the abdominal pain persisted. Temperature remained elevated to no degrees, with the rapid respiratory rate persisting. On February 24, 1932, 2,800 cubic centimeters of dark bile colored fluid were aspirated from the left pleural space following which there was considerable improvement in her general condition. This fluid was negative on culture and negative for tubercle bacilli by 6 weeks guinea pig inoculation and autopsy.

The pleural fluid continued to reform. At thoracentesis was performed 7 times, 1,800 to 2,500 cubic centimeters of fluid being removed at each sitting. The abdomen con-

Fig. 1 Appearance of face with well developed beard and moustache. Note bushy eyebrows.

Fig. 2 Full view of body showing hypertrichosis, masculine pubis, and male type of skeleton.

tinued to be exquisitely tender and in spite of the fact that patient was retaining some nourishment, she continued to lose ground. Operation had been deferred because of the pleural effusion and poor physical condition but by April 14, 1932 the tumor had enlarged to the size of a full term pregnancy and pressure symptoms were of such severity that surgical intervention was deemed imperative.

A pre-operative diagnosis was made as follows: (1) teratoma of the ovary with a preponderance of functioning testicular tissue. (2) the possibility of true hermaphroditism, with destruction of the ovarian tissue by neoplasm probably malignant, and functioning of the testicular tissue, was also considered.

On April 14, 1932, under spinal anesthesia, administered by Dr. M. E. Foster laparotomy was performed by two of us. (Drs. J. M. T. and S. J. W.)

Operation. A low midline incision was made and when the peritoneal cavity was opened approximately 3,000 cubic centimeters of thin brownish fluid escaped. The tumor was found to be semicystic, and of the size of a full term pregnancy extending from the pelvis to the xiphoid process of the sternum. Since it could not be delivered through the incision, which was extended 4 centimeters above the umbilicus, the volume was somewhat reduced by aspirating 4,000 cubic centimeters of thin brown fluid from several cysts. Adhesions to the liver and viscera of the upper portion of the abdomen were broken up and the tumor was delivered. It was then found to be an intraligamentary tumor arising from the region of the left ovary and was removed by dissection from the leaves of the broad ligament and ligation of the pedicle. Raw areas were well peritonized. The right ovary was smooth, brown, half the usual size, and did not show the slightest evidence of formation of graafian follicles or corpora lutea. Both tubes were normal. The uterus was one third the usual size, and apparently otherwise normal. The wound was closed in layers without drainage and the patient returned to her room in good condition.

The convalescence was extremely smooth and it was a notable fact that there was no further recurrence of the pleural effusion. X-ray examination failed to demonstrate chest metastases. The appetite and strength rapidly returned and she was discharged from the hospital greatly improved in good condition May 10, 1932.

A decided change in the appearance of the patient was soon noted. Menstruation occurred for the first time in 4

years on May 22, 1932. It has occurred regularly at 4 week intervals and 3 to 5 days duration since this time. A normal feminine type of voice was noted July 24, 1932. At the present time September 30, 1932 the patient has gained 40 pounds in weight, a marked hypertrophy of the breasts has taken place and the normal feminine habitus has been resumed. The clitoris and prepuce are less prominent. An abnormal growth of hair is still apparent over the chin but it is of a much finer texture and of lighter color. The patient now shaves once in 5 weeks instead of every 3 to 4 days, as formerly.

Gross pathology. A great portion of the weight and volume of the tumor had been lost due to evacuation of multiple cysts. After removal the tumor measured 30 by 20 by 18 centimeters. The weight was 900 grams. The tumor grossly resembled the ordinary multilocular serous cystadenoma. There was a well developed fibrous capsule which had not been broken through and was smooth for the most part except at the uppermost portion which had been adherent to the liver. Large tortuous blood vessels were visible through the capsule. The pedicle was broad and vascular. On section some of the cysts were found to contain masses of soft greyish, friable material. The solid portion of the tumor had the consistency of a normal ovary although ovarian tissue as such could not be recognized. Unruptured cysts contained thin brown fluid.

Microscopic pathology. Sections were cut from many different portions of the tumor and show two distinct types of morphology each of which is undergoing degeneration on one hand and active proliferation on the other. The bulk of the tumor is made up of an atypical arrangement of small round and spindle cells, showing an occasional whorl and a suggestion of groups being bound together in fasciculi. The majority of the nuclei are oval to round, irregular in size, and for the most part hyperchromatic. Mitotic figures are common. A few of the nuclei are pale large and filled with dark granules. In the more cellular portions of the tumor there is no evidence of stroma. A rich network of thin walled, poorly constructed capillaries is generally present.

Some areas of the tumor show a well marked coagulation necrosis and infiltration by small lymphocytes. Other areas give evidence of hemorrhage, and in some fields hyaline degeneration. Where a stroma is present, it consists of an edematous, fibrillated, white connective tissue.

The cyst walls consist of loosely arranged white fibrous connective tissue rather deficient in nuclei, very vascular, and in some areas invaded by an entirely different type of cell which is epithelioid, filled with lipid, and can be identified as an interstitial cell. Figure 8 depicts these cells. There is no epithelial lining to the cysts. It may be conjectured that they have arisen as the end-result of coagulation and liquefaction necrosis of portions of the tumor.

Other blocks show the structure to be undoubtedly epithelial as illustrated in Figure 7. This tissue came presumably from the region of the hilum of the ovary and

Fig. 3. Contracture of vagina and hypertrophy of clitoris. Prepuce well developed.

represents the primary growth. The cells are arranged in the form of irregular medullary cords (Fig. 7) and also as rudimentary tubules (Figs. 5 and 6). As shown the tubules are lined with a single layer of typical columnar to cuboidal epithelium without basement membrane. Cellular detritus and coagulated material have collected in some of the lumens, and in a few definite pear-shaped forms, suggesting typical spermatozoa, can be made out. Such an instance is clearly shown in the lower right hand corner of Fig. 6.

Another special significance is the resemblance of many of the intervening cells as pointed out by Novak, to a rounded and hyperplastic rete ovary structure.

It is therefore our contention that this tumor is primarily an epithelial tumor originating in the hilum of the ovary, and developing from anlagen in the rete consisting of residual undifferentiated cells which have developed along male lines as evidenced by the presence of tubules similar to seminiferous tubules and of typical testicular interstitial cells. This histological evidence is the link of proof needed to stamp this tumor as an arrhenoblastoma primarily which has undergone secondary sarcomatous degeneration.

INCIDENCE

There are no reliable figures on record as to the incidence of this rare tumor. At the present writing of the 26 reported cases none has occurred in the United States. Other cases have occurred, as an undoubted case of Casler's, but have not been reported. Since Meyer's illuminating work additional cases will undoubtedly be added with increasing frequency. The tumor occurs chiefly between the age limits of 21 and 35 years.

SYMPTOMS

1. *Defeminization*. The earliest sign has usually been a persistent amenorrhea with sterility. There is a tendency for the hair of the head to fall out and be short. The breasts atrophy and abnormal deposits of fat may occur over the body. The genitalia of the individual are hypoplastic with the exception of the clitoris. The vaginal

Fig. 4. Gross appearance of tumor

canal is short and contracted, the body of the uterus and cervix atrophic or infantile and the opposite ovary small and entirely free from graafian follicles. The libido has been unchanged until late in the disease.

2. *Masculinization*. The skin is usually dark, rough, and shows a tendency to an acne eruption. There is an abnormal and excessive development of hair over the body. A beard, necessitating in some cases daily shaving is usually present. The distribution of hair over the pubis is of the masculine type. Hair may be present around the nipples. The facial expression is masculine, due to the coarse features and bushy eyebrows. There is an enlargement of the larynx, resulting in a lowering of the pitch of the voice. The skeleton is heavy and there is an inversion of the normal "pelvis to shoulders ratio" of the female. The musculature is correspondingly affected. The clitoris is hypertrophied in most long standing cases.

3. *Pain*. This symptom is usually present because of the pressure produced by a rapidly growing pelvic tumor. This pain may be constant or aggravated by micturition or defecation.

4. *Blood changes*. Secondary anemia is usually present and an increase in eosinophiles and monocytes has been noted. The temperature is frequently elevated. The Aschheim-Zondek test is negative.

Fig. 5. Photomicrograph showing the tubules as they appeared under low power magnification.

5 A restoration of the normal female characteristics occurs after removal of the tumor with remasculinization upon recurrence. Normal pregnancy has occurred after operation in a number of the reported cases.

DIAGNOSIS

The association of a growing pelvic tumor with amenorrhea naturally suggests pregnancy which has been the usual tentative diagnosis made in these cases. The coarsening of the features indicative of beginning masculinization also may be interpreted as the normal accompaniment of pregnancy. However the Aschheim Zondek test will absolutely differentiate the two. The de-

Fig. 6. High power magnification showing structure of tubules. Note pear shaped form in the lumen of one tubule.

feminization and development of outspoken masculine characteristics, in an individual previously normal under the above conditions should certainly suggest this tumor clinically. The finding of evidence of rudimentary testicular cells in the tumor microscopically confirms the diagnosis.

TREATMENT

The treatment is extirpation of the tumor without disturbing the remaining pelvic organs, since one ovary is all that is affected and retention of the secretion of the other is essential to effect return to the normal feminine state. With the present state of our knowledge and for the same reason as above prophylactic deep X ray therapy

does not seem to be indicated. In the event of recurrence deep X-ray therapy should be of value because of the marked sensitivity of germinal epithelium to destruction by radiation.

PATHOLOGY

As a rule the arrhenoblastomata show marked cystic degeneration so that often solid portions may be very sparse. A number of cases of masculinizing tumors of the ovary previously reported as sarcomata or multilocular cystadenomata may fall into this classification after re-study. This is particularly true of the group in which the signs of masculinization have not been outspoken clinically. Histologically there appear to be three distinct groups according to Meyer.

1. *Idenoma testiculare*. Nine of the reported cases fall into this group. The structure is very similar to the tumor of the same name occurring in the testis, and is predominantly tubular. Masculinization clinically is the exception rather than the rule.

2. *Atypical group*. The 11 cases falling in this group showed marked masculinization in 9 instances. The case here reported is an additional instance. The structure is sarcoma like and the tubules often rudimentary.

3. *Intermediate group*. In all 6 cases collected by Meyer masculine changes of a slighter degree were present. Morphologically these tumors resemble group 1 in some areas and group 2 in others.

With the present state of our knowledge concerning sex differentiation, Meyer's theory of the origin of these tumors from undifferentiated germ cells in the hilum of the ovary which have not been utilized during embryonic development of the ovary but which have retained their sexual

potency and remained dormant until some such time when for an undetermined reason proliferation takes place, is most compatible. Pick's theory that these tumors develop from an ovario-testis is not tenable in view of the fact that these patients do not exhibit evidence of bisexuality from birth and that true hermaphrodites have never been known to develop tumors which defeminize and masculinize.

It is an interesting speculation why the most marked changes toward masculinity occur in the atypical group with sarcoma like structure. Those tumors in which the tubular arrangement is best developed are rarely associated with alterations in the secondary sexual characteristics of the individual, and in true seminomata, practically never. In the instance here reported, the sarcomatous appearance almost completely masks the tubular structure, although clinically extreme masculinization had occurred and return to femininity is in progress after extirpation of the tumor. Meyer is of the opinion that under certain conditions a transition is possible from epithelial to connective tissue. It has been assumed that the endocrine secretion of the testis, and presumably also the hormone affecting the secondary sexual characteristics of the body is a product of the interstitial cells of Leydig, which exist under normal conditions in the form of irregular cords and which cannot be distinguished histologically as epithelial or mesodermal, although embryologically the bulk of the evidence is in favor of origin from the latter. It is the opinion of one of us (F. K.) that possibly an excessive amount of this hormone is produced by this hyperplasia of residual undifferentiated cells with definite male tendencies in the hilum of the ovary, or in other words a hyperplasia of anlagen of Leydig's cells, and that the tubular formation is merely another form of expression of tumor function and of the underlying tendency toward masculinity. Since normally interstitial cells cannot be classified exactly from the standpoint of tissue groups, it is tenable that under abnormal conditions this confusion should be even greater. Meyer has also suggested the possibility of a secondary sarcomatous degeneration of the stroma of the tumor.

In this particular case, recurrence will undoubtedly take place, since the removal was necessarily incomplete because of adhesions to the liver. Light may be shed upon this question by a study of the morphology of the recurrence. It must be emphasized however that while primary ovarian sarcomata are not uncommonly seen, masculinizing changes associated with such tumors only occur where epithelial elements

Fig. 10. Five months after operation. 40 pounds weight gain; return to general body type of feminine contour.

having the histological structure described by Meyer under the term arrhenoblastoma are present.

PROGNOSIS

These tumors are predominantly malignant. In the 8 cases reported up to 1909, only 1 was malignant. In 13 cases collected by Strassman since this time, all have been malignant except one. The case here reported shows malignant degeneration. This malignancy, however, is usually relatively benign as recurrence and metastases do not usually make their appearance before 6 to 7 years.

SUMMARY

This case of arrhenoblastoma of the ovary is reported as the first case from the United States,

Fig. 11. Compare with Figure 1. Five months after operation. Lessened hair growth, of finer texture. This growth of beard of 3 weeks' duration. Figure 1 of 4 days.

and the twenty-seventh in the literature in order to call attention to this condition which if generally appreciated and recognized would offer an exceedingly fertile field for increasing our knowledge of endocrinology by means of animal experimentation with tumor transplants, extracts and transudates.

NOTE.—The authors wish to express their indebtedness to Dr. Emil Novak, of Baltimore, Md., for his valuable suggestions; to Dr. J. L. Goforth, of Dallas, Texas, for the histological sections which made this study possible; and for the preparation of part of the photomicrographs; and to Professor Robert Meyer, of Berlin, Germany, for his study of the tumor and photomicrographs.

TREATMENT OF FRACTURES OF THE BONES OF THE LEG

JAMES WILLIAM MARTIN, M.D., F.A.C.S., OMAHA, NEBRASKA

CURRENT surgical literature is so full of articles dealing with the use of skeletal traction in the treatment of fractures that any further contribution along this line might be promptly regarded as superfluous. The writer is emboldened to submit this paper dealing specifically with treatment of fractures of the bones of the leg because of the conviction that the technique to be described has both simplicity and dependability to recommend it.

Those who have had wide experience in treating fractures will readily agree that fractures of both bones of the leg often present an especially troublesome surgical problem. The fact that many of these fractures are compound adds, of course, to the difficulties. Whichever the type of fracture that is, simple or compound, extensive injury to the soft parts and serious disturbance of the local circulation about the ends of the fractures are frequent accompaniments. One need reflect but a moment upon the incidence of delayed or non union in these fractures to agree with this state

ment. When the position of fragments approximates anatomical perfection and there is no local infection or general constitutional factor to explain the failure of prompt union there can be only one cause of delayed union, namely a disturbance in the local physiology induced by tissue and particularly minute blood vessel trauma. Any reduction procedure which adds more traumatism to the fracture site is physiologically wrong and should be avoided.

Obviously the procedure which adds the greatest burden to the already embarrassed local physiology is open reduction and direct internal fixation with non absorbable material. This does not mean that open reduction and fixation with metal will invariably be followed by failure; common experience disproves that this is a universal truth. But the implication is that this method will inevitably show a rather high percentage of poor results in terms of delayed or absolute non union inasmuch as it is inimical to the normal healing process.

Fig. 1 After the skeletal traction device, either Steinmann or Kirschner type, is in place the knee is flexed over the upper cross bar of the frame and the traction bow is hooked onto the turnbuckle. (The frame is made of half inch pipe except for the upper sliding unit which is one quarter inch.)

Fig. 2 The upper cross bar is pulled up as far as possible depending upon the length of the particular leg, and it is held in place by inserting the keys (seen here attached to the small chain). It will be noted that there is ample room for application of the cast.

Fig. 3

Fig. 3. Case. Compound comminuted T fracture of tibia extending into ankle joint, and simple transverse fracture of fibula. Patient a male aged 35 years.

traction on frame and fixation in plaster. Note distraction or overpulling of tibial fracture.

Fig. 5. Case 1. Correction of overpulling and angulation by removal of section from cast.

There can be little justification for the internal metal fixation method in these leg fractures if it is quite uniformly possible to effect by means of the closed method an approximately anatomical reposition of fragments. It is the purpose of this paper to describe a technique of closed reduction in fractures of the bones of the leg which does insure this desideratum.

TECHNIQUE

This technique is simply the application of traction in an efficient completely controllable manner followed by fixation in such a fashion that the correction or reduction of the displaced fragments is maintained with accuracy and permanency. Traction applied by the operator tugging with his unaided hands on the foot of the patient while an assistant vainly tries to exert countertraction on the knee, thigh, or crotch is not efficient traction because though reduction may be momentarily obtained, it cannot be

maintained during the application of the fixation apparatus whether cast or splint. Traction applied on a fracture table through adhesive tape and moleskin stuck on the skin of the leg is very frequently not efficient traction, particularly when fractures are situated low in the shafts. Traction to be efficient in these fractures must be skeletal traction. It must be employed in such a way that reduction will be obtained immediately so that definitive fixation of the fragments may take place immediately. Nature does not wait 2 or 3 weeks or any other period before starting the work of healing. The "stimulus of incompleteness" exerts its influence at once. A skeletal traction technique which carries out gradual reduction by weight and pulley over a period of several hours or days is prone to too many accidents. It frequently does not give the operator the complete accurate, mechanical control of the situation which he should have and in addition it may be distressing to the patient.

Fig 6

Fig. 6 Case 2 Anteroposterior roentgenogram taken before reduction

Fig 7

Fig. 7 Case 2 Anteroposterior view after reduction.

Fig 8

Fig. 8. Case 2 Lateral view after reduction.

The mechanical requirements of reduction and fixation are well met in the following technique:

1. A skeletal traction device either Steinmann pin or Kirschner wire is inserted through the calcaneus or just above it. Placing the pin or wire completely through the bone is preferable because it gives more certain control of the rotation of the distal fragments. (In some instances tongs inserted into the malleoli are preferable e.g. when a fracture of the calcaneus is present in addition to the tibial and fibular fractures.) If the Steinmann pin is used, the unjointed pin and not the type that screws together in the middle should be selected. The latter breaks too readily.

2. The patient is next moved down on the table so that his buttocks are opposite the lower edge of the table and his knee on the injured side is flexed to a right angle over the upper cross bar of the frame. The uninjured leg may be supported on another stand.

3. The Kirschner wire or Steinmann pin device is next attached to the turnbuckle fastened to the lower cross bar of the frame.

4. The adjustable upper cross bar of the frame is next pulled up as far as possible (depending

upon the length of the leg) carrying the flexed knee with it, and the keys are inserted into the uprights to hold the cross bar in place.

5. Further traction is then obtained by twisting the turnbuckle until the fragments are pulled into place. Frequently reduction is perceived by the hand applied to the sides of the leg at the fracture level. A further check on length is had by comparing the measurements from the knee joint line to the tip of the internal malleolus on both legs in corresponding positions. And finally roentgenograms of the leg are made in the anteroposterior and lateral positions, a portable unit being wheeled into the operating room for this purpose.

6. While the films are being developed, application of a plaster cast is begun with the knee in right angle flexion and traction still maintained. Molded splints are used as the foundation for the cast and the cast is fashioned in sections above and below the line of fracture. (No plaster is wrapped around the upper cross bar of the frame in order that the leg may be eventually lifted off the frame without difficulty.) By the time the upper and lower segments of the cast are finished the roentgenograms have been developed

Fig. 9A

Fig. 9B

Fig. 10

Fig. 11

Fig. 10. Case 3. Anteroposterior view after reduction.
Fig. 11. Case 3. Lateral view after reduction.

and are available for examination. Any further correction of the position of fragments which is indicated is easily obtained and the two segments of the cast are joined together with a few additional turns of the plaster bandage. The pin or wire is removed from the heel as soon as the cast has hardened unless the fracture is severely comminuted in which case there may later develop a further need for skeletal traction as will be mentioned later. The hiatus in the cast at the back of the knee found when the leg is lifted off the frame is filled in with a short molded plaster splint and a few circular turns of plaster bandage.

7 As soon as the cast is completed, it is slit or cut through its entire length, usually on its external lateral side to lessen circulatory interference. This is a very important step and should never be omitted. The cast is prevented from becoming too loose by encircling it in three or four places with webbing straps or simple adhesive tape.

Reduction is, of course, performed under general inhalation or spinal anesthesia. In my experience the latter is much better because it gives such complete muscle relaxation.

If the surgeon is so situated that immediate X-ray examination during the reduction procedure is not available measurements and the gross appearance of the limb must be relied upon, and the cast completed at once. In this case the wire or pin is left in the heel and check up roentgenograms are made some hours later or on the following day. If these films reveal the need for further traction or correction of angulation deformity the plaster cast, provided it has been carefully applied affords the mechanism for complete correction. If the fragments are end to end but in faulty alignment the cast is cut through for about three fourths of its circumference at the level of the angulation deformity, the angulation is easily corrected without anesthesia and the corrected position is maintained by a few turns of plaster bandage re-inforcing the plaster cast. If further traction is needed the cast is cut through its entire circumference at the level of the fracture traction is again applied to the heel pin sufficient to correct the shortening, and finally the proximal and distal portions of the cast are joined together with molded strips and a few turns of plaster bandage. Conversely if the fragments have been over

pulled a ring of plaster of the proper width is removed from the cast at the level of the fracture and the two segments again fastened together with plaster

POST REDUCTION TREATMENT

There is no need for haste in removing the pin from the heel, but similarly there is no point in leaving it in place after it has served its purpose. In simple fractures the pin is removed as soon as the check up roentgenograms reveal no need for further traction. In compound fractures the time for removal of the pin depends upon the absence or presence of frank infection in the fracture wound. If no infection has developed at the fracture site by the end of the first week it is concluded that there will be no further need for the pin and it is removed. If during this period infection extensive enough to require removal of the cast has occurred the pin is left in place and utilized during subsequent treatment of the injured limb in a Thomas splint.

The thigh portion of the plaster cast is discarded about the end of the fourth week to permit mobilization of the knee and at this time a walking iron is fastened to the leg cast with a few turns of plaster bandage. The walking iron should be applied with care or it will prove more of a hindrance than an advantage. The long axis of the iron should coincide with the long axis of the leg and the iron should extend not more than 2 or 2.5 inches below the cast, it being assumed that the foot has been correctly placed at a right angle with the leg. The sole and heel of the shoe on the uninjured foot usually need to be elevated a little to equalize the length. Weight bearing is now freely permitted first with crutches until the weakened quadriceps femoris muscle has regained some strength and then with a cane. The cast is usually completely discarded about the tenth week in the severer fractures. The criterion of course is the roentgenological and clinical evidence of union. The period of total disability should not exceed 14 weeks in a patient employed at heavy common labor provided there has been no infection or other complication.

SELECTION OF CASES

This technique of immediate reduction by means of skeletal traction on the specially constructed frame followed by immediate fixation in plaster is applicable to practically all fractures of the shafts of the tibia and fibula with considerable displacement whether simple or compound. In compound fractures débridement is sparingly performed, only the skin edges and the frankly

devitalized muscle tissue being excised. The wound is packed with vaselized gauze and no attempt is made to bring the skin edges together though a few silkworm sutures are inserted chiefly to control oozing. Copious dressings are then laid over the wound and bandaged in place after which the pin or wire is inserted into the heel just as in a simple closed fracture. No window is cut in the cast and the compound fracture wound is not dressed as long as the patient's temperature does not become alarming. If frank infection does develop it is of course treated according to common surgical principles.

ADVANTAGES OF THE TRACTION FRAME

The chief advantage of the traction frame over the standard fracture tables in the treatment of the fractures here under consideration is that it permits traction on the leg with the knee flexed to 90 degrees with a minimum of bother and a maximum of control. And there can be no difference of opinion regarding the preferable position of the knee during reduction of these fractures: the right angle flexion position is by far the better. It is better than the extended position because it gives additional relaxation to the calf group of muscles because it affords a perfectly fixed point of countertraction and because it renders redistribution of the reduced fragments after application of the cast impossible. I think this particular frame has perhaps some advantages over the apparatus used by Boehler inasmuch as angulation at the site of the fracture is less likely to occur with the leg in the dependent or vertical position than it is with the leg in the horizontal position; furthermore this frame interferes less with application of the plaster cast and finally it is simpler to construct. Other advantages of the frame besides its efficiency are its inexpensiveness and portability. It may be used for fractures other than those of the tibia and fibula though this does not come within the scope of this paper.

SUMMARY

1. Open reduction and internal fixation by means of non-absorbable material in fractures of the bones of the leg is too frequently followed by delayed or non-union.
2. Closed reduction will give a high percentage of good results in terms of shortened convalescence and minimal functional impairment provided skeletal traction is properly employed.
3. A technique of closed reduction by skeletal traction, and details of post reduction treatment are given and a simplified traction frame is described.

COINCIDENT SURGICAL EXPOSURE AND RADIUM THERAPY IN THE TREATMENT OF EXTENSIVE CERVICAL CANCER¹

ARTHUR H. CURTIS, M.D. F.A.C.S., Chicago

THE number of cures of cervical cancer varies roughly from 25 to 30 per cent in the major clinics of all countries, irrespective of whether the growth is removed or is treated by radium. Generally speaking the results are very satisfactory in cancers not progressed beyond Stage I in which cases the growth is still limited to the uterus.

In Stage II cancer of the cervix, in which the growth has progressed beyond the uterus but is still relatively limited in extent, the prognosis is dubious. In Stage III cases, with induration of the parametrium and more or less fixation of the uterus, the outlook is well-nigh hopeless. In brief *radical operation and radium treatment are relatively unsatisfactory both in Stage II and in Stage III cases*, and it is apparent that other procedures are required for successful management of patients with these more extensive lesions. Radical operations have evidently reached their limit of efficiency and we therefore turn now to improved radiation and allied measures for further help.

In the paucity of radium treatment, attempts to obtain cures with massive doses resulted in a distressingly high incidence of destructive lesions of the adjacent viscera, often terminating in fistula formation or death. We learned relatively early that the pelvic viscera are highly susceptible to injury from radium burns and, particularly, that many cancers can not be cured because proximity of the bladder inhibits efficient radiation. With this in mind, I have for several years made a practice of separation and upward displacement of the bladder to permit more extensive use of radium in this region without introducing the danger of vesical fistula. The additional area thus made available for radiation has permitted intensive treatment of several cases of cervical cancer which could not otherwise have been satisfactorily radiated.

The value of dissection and retraction not only of the bladder but also of the other vulnerable tissues has become more and more apparent and has eventuated in a combined method of surgical exposure and coincident radium application. The suggestions advanced in this paper pertain particularly to treatment of the Stage II group of cases and to the less advanced cases of the Stage III group in which there is some hope of cure.

PROCEDURE

The necrotic cervical growth is treated with surgical diathermy or prophylactic radiation at least 3 weeks prior to operation. Preliminary deep X-ray therapy may serve equally well in healing the sloughing cancerous surface.

Under anesthesia, a preliminary pelvic examination is made to determine the extent of the growth and the amount of intervention required. Exposure of the cancer bearing uterus and adjacent cellular tissues is now undertaken. With blunt dissection, the bladder is mobilized upward, the cervix encircled with an incision as in making a radical vaginal hysterectomy, and the *vaginal mucosa palisadingly dissected laterally and posteriorly along natural lines of cleavage*. The body of the uterus and the regions of the broad ligaments and cardinal ligaments are now well visualized. With the organ half delivered broadside vaginally the bladder safely anchored in its elevated position with a catgut suture holding it high on the uterus, and the paracervical tissues exposed, a massive radium treatment is possible. Radium needles or radon seeds are now inserted where needed, near to or into the cervix or far from it, as indicated with assurance of safety of the adjacent vulnerable organs (Fig. 4). Although the ureters are subject to possible injury they are considerably retracted incident to the dissection and displacement of the bladder and are relatively immune. Preliminary ureteral catheterization may merit consideration in selected cases, but we have not resorted to it. Injury of a uterine artery is a possibility. I have not yet seen that complication despite many years custom of introducing radium needles into the cervical parametrium. Palpation of the artery preliminary to burying a radium needle in its vicinity appears unnecessary.

After burying the radium needles (or radon) as described, a chain tandem of radium capsules is inserted into the uterine canal in the usual manner. A vaginal pack completes the procedure.

Until further experience warrants, the total radiation should not exceed 3,500 millicuries. Even that amount may be excessive.

REPORT OF CASES

CASE. Patient was admitted to Passavant Memorial Hospital January 9, 1933. She was a married woman of 58

Fig. 1

Fig. 2

Fig. 3

Fig. 1. The bladder is mobilized and displaced upward.
Fig. 2. The cervix has been encircled with an incision. Early stage of dissection of the vaginal mucosa.

Fig. 3. The vaginal mucosa is painstakingly dissected anterolaterally and posteriorly along natural lines of cleavage.

with two healthy children. Menopause occurred at 50 years of age, slight spotting of blood 10 years later in September 1932. Rather free bleeding on one or two occasions thereafter. No pain.

Examination. Patient's general condition was good, heart and lungs were normal, blood pressure 130/85, red blood count, 4,720,000, hemoglobin 75 per cent, Wassermann, negative. Vaginal examination revealed some urethrocele with incontinence, a relaxed perineum with slight rectocele and a long narrow funnel shaped vagina. The cervix, high up in the vaginal vault, nearly 4 inches from the vulva, presented a friable new growth involving both lips. The cancerous tissue bled freely on manipulation. The wide extent of the growth in the cervix suggested some invasion of the parametrium. The uterus had limited mobility but there was no definitely demonstrable invasion of the broad ligaments.

Operation. On January 10, under nitrous oxide anesthesia, delivery of the cervix to the vulva was accomplished despite the markedly elevated position and limited mobility of the uterus. Extension of the growth was in close proximity to the bladder but the latter could be separated and was mobilized and advanced $1\frac{1}{4}$ inches higher on the uterus. A moderate treatment with surgical diathermy was administered to destroy the necrotic local growth.

Microscopic study revealed a richly cellular cancer containing many epithelial pearls and cells of varied size provided with abundant mitotic figures.

On February 16 the patient was re-examined, this time under ethylene anesthesia. There was found gross evidence of remaining malignancy of the anterior lip extending rather deeply into the cervical canal and laterally somewhat into the left broad ligament. The sloughing surface of the tumor was well healed.

Surgical procedure and radiation. The bladder which had returned to its normal position since the diathermy treatment, was readily mobilized and displaced upward. A circular incision around the cervix and blunt dissection of the vagina along natural lines of cleavage exposed freely the pillars of the bladder anteriorly, the broad ligaments and cellular tissues anterolaterally and the pillars of the rectum posteriorly. The bladder was now sutured to the body of the uterus in its reflected position in order to keep it out of the way during radiation. Seven radium needles were inserted about the cervix, chiefly laterally into the

bases of the broad ligaments. Seventy five milligrams of radium in capsules, in tandem were placed in the uterine canal. All told a dosage of 3,000 milligram hours was given.

Postoperative course. The patient made an uneventful convalescence and left the hospital in a week. A notation on re-examination April 20 1932, reads as follows: The cervix appears to be entirely healed and is freely movable. There is no evidence of remaining displacement of the bladder or of the reflected vaginal walls, no pelvic induration, nodulation or tenderness. The patient feels fine, has no vaginal discharge, no urinary or bowel symptoms, is gaining weight, has a splendid appetite and seems to be well on the way to a clinical cure.

CASE 2. Patient was admitted to Passavant Memorial Hospital December 15 1932. She was a married woman of 46 formerly a graduate nurse. One pregnancy at the age of 18, terminated by spontaneous abortion in the fifth month. Menstruation had always been regular of the 28 day type, duration 5 days, until the menopause one year ago at the age of 45 years. Malaise and slight pelvic distress led the patient to insert a finger into the vagina 4 months prior to entrance into the hospital. She felt a mass but did nothing further until 3 weeks prior to entrance, at which time she palpated a nodulation like a cauliflower. A dirty blood tinged discharge now appeared and persisted, with increasing bloody flow as time progressed.

Physical examination revealed the patient to be in fairly good general condition, heart and lungs, negative, blood pressure, 130/80, red blood count 4,160,000 leucocytes, 21,300, hemoglobin, 70 per cent, Wassermann, negative. The pelvic findings are included in the detail of the operations recorded below.

Surgical diathermy treatment. On December 17 under nitrous oxide anesthesia, the cervix was found to be enlarged to double normal size by a cauliflower like necrotic tumor which involved the entire vaginal portion of the cervix and slightly invaded the vaginal wall in all directions. It was recorded that submucosal extension was apparently still more widespread than the surface growth and infiltration anteriorly had apparently progressed to the floor of the bladder if not into it. "The generous sized uterus is freely movable although there must be some broad ligament invasion."

With painstaking delivery, the cervix was brought beyond the level of the vulva. Tissue was removed for biopsy

Fig. 4.

Fig. 5.

Fig. 4. The body of the uterus and the regions of the broad ligaments and cardinal ligaments are now well visualized. With the uterus partially delivered, vaginally the bladder safely anchored in its elevated position with a cat gut suture, and the parametrial tissues exposed, radium needles or radon seeds are now inserted where needed, as indicated, with assurance of safety of the adjacent vulnerable organs.

Fig. 5. Radium needles and chain tandem radium capsules in position. The placement of the needles is accurately portrayed in Figure 4.

Extens surgical diathermy was given, moist gauze packing being employed to protect the adjacent tissues.

Histological study of the growth revealed an anaplastic epithelial cell carcinoma of the cervix.

Surgical procedure and radiation. January 17, 1933, ethyl-ene anesthesia. The diathermy treatment of a month previous, together with changes wrought by the cancerous growth, had resulted in complete destruction of the anterior cervix and a major portion of the posterior part. Slight dissection revealed the bladder lying on the uterine canal with almost no intervening tissue. The uterus was mobile. Extension of the growth anteriorly apparently had not involved the bladder, but it was much distorted and its separation and upward displacement without injury was accomplished only with difficult, painstaking dissection. Lateral and posterior dissection of the vagina was followed by further tedious complete separation of the bladder from the uterus, including opening of the anterior cul-de-sac. An excellent delivery of an apparently hopelessly entangled and distorted uterus was obtained. The remaining shrunken organ was only 3 inches in length. Some fibrous and residual infiltration (apparently cancerous) persisted in the para-uterine cellular tissues, but evidently not beyond access of radiation now that the dissection had delivered the uterus and had displaced the vulnerable bladder and ureters. A palisade of 8 radium needles was inserted into the tissues around the cervix and into it and one 50 milligram tube of radium was placed in the uterine canal. A total of 3,000 milligrams was administered.

Rectovaginal examination, two and two-thirds months subsequently April 5, 1933, revealed healing far progressed. The region of the uterus and its vicinity which had been raw and necrotic during the interval following the operation, was now almost healed. The retracted tissues (still somewhat retracted a month earlier) now covered the stump nicely. The mobility of the uterus remained limited but the outlook appeared encouraging.

CASE 3. Patient was admitted to Parnassus Memorial Hospital November 3, 1931. She was 42 years of age, had previously been married, and had been divorced for 10 years. One birth, with normal delivery occurred at the age of 31. Menstruation had always been regular 28 day type, duration 4 to 6 days, with normal, painless flow until present trouble. Routine examination by a physician 3 months ago revealed a raw, ulcerated area on the cervix. No improvement with local treatments. She flowed persistently following regular period 1 month prior to entrance and thereafter bled rather freely alternating with periods of spotting, until time of entrance.

Physical examination revealed a rather pale, fairly well nourished, somewhat nervous patient. Heart and lungs were negative; blood pressure, 116/66; red blood cells, 3,810,000; leucocytes, 8,550; hemoglobin, 75 per cent.

Examination and radium treatment. November 3, ethyl-ene anesthesia. Although superficially limited, the friable, bleeding lesion near the external os of the cervix was found to be an extensive endocervical cancer apparently originating within the cervical canal. The fundus was of generous size, retrodisplaced, mobile. Gentle removal of the endocervical cancerous debris left a cavity half the diameter of the cervix, beyond which the growth had apparently extended into the left parametrium. The prognosis appeared unfavorable. A palliative intra-uterine treatment with radium capsules was given.

Microscopic examination revealed a loose fibrous stroma containing islands of a squamous cell, group 3, middle ripe growth.

On January 26, 1932 the patient was again given ethyl-ene anesthesia. The fundus of the uterus was found to be large and mobile. There was a palpable thickening anterolaterally on the left. The cervix was cancerous, the lower uterine segment slightly obstructed. Dilatation yielded some retained serohemorrhagic fluid.

The bladder was separated from the cervix, displaced upward and anchored with one catgut suture. Eight radium needles were buried in a palisade encircling the cervix and 75 milligrams of radium in 2 capsules in tandem were placed in the canal. A total radiation of 1,750 millicuries was given.

Surgical exposure and radium treatment. The patient was kept under observation, with bimanual rectovaginal examination at monthly intervals. Her isolated social status and the need of a complete understanding of her condition because of her dependent child led to a frank discussion of the prognosis. The clinical course continued excellent but there remained an infiltration to the left parametrium. After prolonged temporizing it was finally decided that radical intervention was preferable to expectancy this despite the fact that increasing infiltration could not be determined with certainty.

Operation February 14, 1933, ethylene anesthesia. As a result of the previous radium treatments, the uterus presented the appearance of a clinical cure. The external os was sealed, the canal $2\frac{1}{2}$ inches in depth, the size of the uterus normal. The bladder was flush with the cervix and there was considerable edema in the region of the pillars. There was moderate uterine mobility with some palpable "fullness" in the left parametrium.

The bladder was separated and displaced upward 2 inches. A circular incision around the cervix was followed by separation of the vaginal mucosa posteriorly and laterally thus exposing the broad ligaments thoroughly and extending upward posteriorly to the pillars of the rectum. With the uterus thus mobilized and the bladder held up by a fixation suture, 7 radium needles were thrust into the left broad ligament, and high into the cervix anteriorly and less high posteriorly and laterally all under digital control of the left hand, with the forefinger in the vagina and the middle finger in the rectum to protect against bowel injury. Seventy five milligrams of radium in 2 capsules were placed in the uterine canal. A total radiation of 3,075 millicuries was given.

Postoperative course. The patient left the hospital after an uncomfortable week. There was no palpable exudate. A month later the uterus was somewhat descended, heavy, "lumpy" raw discharging and apparently still uncovered by mucosa (speculum examination was avoided because of excruciating tenderness).

Very recently 3 months after operation and radiation, the patient returned to the hospital because of pelvic distress. Speculum examination revealed considerable necrosis of the cervical portion of the uterus, and some of the adjacent parametrium. There was a rather free serous discharge containing fragments of debris. The bladder and ureters, apparently in excellent condition, had returned to normal position. The lateral vaginal walls were no longer retracted. Rectovaginal examination indicated a normal bowel and revealed no pelvic exudate, but some brawny fixation, and the patient experienced discomfort in the region of the rectosigmoid. Despite the rather extensive tissue destruction, which was more than anticipated or desired, it appeared that the process was subsiding without serious complication.

In view of the fact that these three patients have been cured for within the last several months it is evident that a prognosis as to the ultimate outcome is unwarranted. Yet the fact that intensive radiation can be accomplished without injury to important structures must lead

to a more encouraging outlook in cases of this character.

Complete surgical recovery has occurred in one of these cases, with accompanying gross disappearance of the growth and free mobility of a now apparently healthy uterus. A second patient has made an almost complete surgical recovery, except for some irregularity in contour of the uterus incident to partial destruction of the cervix and lower uterine segment. The third patient has, at the present time, some necrosis of the cervix and adjacent cellular tissues with considerable associated pelvic cellulitis and profuse discharge which contains some fragments of tissue. The bladder and ureters are in excellent condition despite the nearby destructive process; this bladder would undoubtedly have been injured by the radiation had it not been spared by preliminary dissection and retraction at the time of treatment.

The raw surfaces created by the dissection in these cases apparently need cause no concern. The dissected tissues gradually fall back into their normal positions after removal of the radium. The use of sutures is unnecessary. Even the bladder reflection despite the anchoring suture of catgut which holds it in upward displacement during radiation quickly resumes its natural position.

Further experience may require modification in the detail of the procedure. We are most concerned with the value of the underlying principles involved.

It has been thought by some that implantation of radon seeds into the cancer bearing pelvic tissues at the time of abdominal operation may prove to be a decided asset in our fight against cancer. Gellhorn has made intra-abdominal implantations of radon, under guidance of the other hand, within the vagina. He then closes the abdomen and makes the usual vaginal introduction of radium. Perhaps intra-abdominal placement of radon may be advantageously employed in conjunction with the procedure herewith suggested.

CONCLUSIONS

1. The feasibility of coincident surgical exposure and radium therapy in the treatment of extensive cervical cancer has been demonstrated in three cases.

2. It is my belief that acceptance of the principle of combined vaginal approach and appropriate radium therapy will result in an improved prognosis in many relatively extensive cases of carcinoma of the cervix which have heretofore had a dubious outlook.

THE TREATMENT OF DUODENAL FISTULA

INCLUDING A REPORT OF TWO NEW CASES AND A REPORT OF A NEW BUFFER SOLUTION

JOHN A. KITTELSON, M.A., M.D. SIOUX FALLS, SOUTH DAKOTA

ANY surgical complication having a reported mortality of 50 per cent must of necessity be studied carefully. Furthermore when death may supervene 1 or 2 days after the complication arises, it certainly behooves the surgeon to be well acquainted with its diagnosis and the various kinds of treatment, so that he may start the most efficient treatment immediately. A patient with duodenal fistula becomes debilitated with extreme rapidity by inanition, dehydration, and the loss of chlorides. It becomes one of the most ravaging and one of the most disconcerting conditions with which the gastro-intestinal surgeon has to deal. It inspires dread both because of its high mortality and its extremely rapid course.

An attempt is made in this paper to review the literature on the subject since 1865—94 cases—and to add 2 of our own, making a total of 96 cases. This is the largest series of cases reported in any paper so far. There are but few reports of the condition before 1900. When recognized it was dealt with haphazardly and the results were consequently poor. We found no case with recovery reported in medical literature before 1900. During this period, the treatment was medical and altogether conservative. Possibly for this very reason, the treatment became surgical for the next 25 years. The mortality rate which had been 100 per cent, dropped to between 43 and 50 per cent. Since 1917 the treatment has again become medical but based on radically different principles. The mortality rate has dropped markedly. The late reports on the present treatment are so good that it may become the treatment of choice, since at least one good sized series shows 100 per cent recovery.

Lilienthal reported the first two cases of duodenal fistula treated by surgical means, in 1901. Two years later von Cackovic collected 6 additional cases from the literature, all of whom died after having been treated conservatively. In 1917 Melchior reported on 14 cases, while Colp reviewed 53 cases in the literature and added 8 of his own in 1923. In the same year Cameron reported on 29 cases. In 1929 Potter (50) reported on a series of 9 cases treated medically with no deaths. These various reports seem to prove that duodenal fistula is not so rare a condition as one

might at first conclude. The success of recent medical treatment definitely disproves the view of Pannet who stated that "duodenal fistula never healed without surgical aid and if left was invariably fatal."

Duodenal fistula may result from various causes and the point of exit may be almost anywhere on the abdomen or on the back. Trauma of the duodenal wall may result in necrosis and abscess, which in turn may gravitate and rupture far from its origin. In Forster's case of retroperitoneal perforation, the pus ascended along the great vessels and localized in the neck. Wagner and Fenwick cite cases in which the burrowing fluid localized in the inguinal region and autopsy proved the connection with the retroperitoneal second portion of the duodenum. Other such cases are cited by Koerte, Esau, and Hinton (35). Quite often the fistula is the result of operative interference on or near the duodenum. The wall of the duodenum may become traumatized or its blood supply compromised. Mayo (39) cited 3 cases in which the duodenal wall was injured in performing right nephrectomies. Other cases are cited by von Cackovic, Payr and Thevenard. The duodenum may also be injured easily in dissecting away adhesions during gall-bladder operations. Such cases were recorded by Fink, Meyer and Merk. Fistula may also follow accidental opening of the duodenum or transduodenectomy for the extraction of stone in the common bile duct. Various types of resection of the stomach may be followed by fistula as is shown by the cases cited by Melchior, Makkas, Kelling, and Cameron.

Perforated duodenal ulcer, when this condition has been treated with simple suture is another very common cause of duodenal fistula. The greatest care must be taken that the suture lines are perfect. A minute leak will enlarge shortly and result in fistula. The natural activity of the stomach and duodenum encourages such a result. As the stomach empties its contents into the duodenum, the duodenal pressure is greatly increased and sutures cut through the brittle wall. Many such cases are cited in Table I.

Gauze packing is one of the most important contributing factors in the formation of duodenal fistula. Particular stress was laid on this point by

Cameron. In this location, there is a great deal of edema of sutured tissue. Gauze packs increase this edema possibly to the point of interfering with the circulation. There may be also a slight adherence between the sutures and the gauze. Then, upon the removal of the gauze naturally slight pulling on the sutures results and this would in turn result in some enlargement of one or more suture openings. Even such a small opening may become enlarged rapidly by the action of the trypsin of the pancreatic juice and become the starting point of a fistula. Furtwangler stated that most severe forms of fistula resulted from leaking sutures.

Infection of the suture lines is undoubtedly another contributing cause. This is especially true in cases of ruptured duodenal ulcer. Infection prepares the way for leaking sutures and for perhaps rupture of the entire suture line by increasing the edema and by rendering the bowel wall more brittle. Due to their injury the tissues are below par. Their blood supply is compromised. The natural local resistance of the tissue is greatly lessened due to this lessened nutrition.

The strong digestive action of the pancreatic trypsin is the most important primary cause of duodenal fistula. It attacks the proteins of the living tissues and is highly destructive. It is this ferment that seeps through small suture leaks and rapidly enlarges them. Furthermore there is no healing while the trypsin remains active in the wound. The whole wound usually breaks open and rapidly enlarges. Potter stated, in his discussion of the digestive activity of the fistular fluid that the bile played a minor rôle although it did attack the fat of the abdominal wall. The trypsin was by far the most damaging, he stated.

The diagnosis offers no great difficulty in the great majority of cases especially if the complication of duodenal fistula is kept in mind. According to Table I, the time of onset may vary from 2 days to several months. On the average the time of onset is from 5 to 14 days. Often-times the onrush of the fistular fluid follows the gauze pack as it is removed. When the tryptic fluid has once broken through the onset of the fistula is very rapid and the amount of fluid coming through may be enormous. The operative wound usually breaks open along its entire length. The wound becomes extremely tender and the skin around the wound edges becomes inflamed and bleeding. Most patients complain of a feeling of severe burning in the entire wound and the adjacent skin surface. The fat in the adipose layer becomes digested and the wound takes on an excavated appearance. The walls of

the blood vessels along the margin of the wound may become digested and bleeding from the wound may be of alarming proportions. The chemical reaction of the fluid discharge is usually strongly alkaline in the worst type of fistula. Should the fluid discharge be acid in reaction, the fistula is probably suprapapillary in origin.

There seems to be considerable variation in the destructiveness of various fistulas and in the toxemia accompanying them. This of course depends on the size of the fistular opening and the tortuosity of the tract. The point in the duodenum where the fistula originates is another very important factor. It is either suprapapillary or infrapapillary according to whether it is above or below the papilla of Vater. This distinction is of great prognostic value since suprapapillary fistulas certainly are not nearly so destructive as those originating below the papilla of Vater. However fistulas that follow the Billroth II type of operations usually contain bile and these fistulas are excellent examples of the suprapapillary type. It is also well known that pancreatic ferments may be carried retrograde by antiperistaltic waves of the duodenum. Payr reported an infrapapillary fistula with absence of bile and pancreatic ferment in the secretion.

The type of duodenal origin of the fistula probably has a great deal to do with the amount of the discharge. It is easy to conceive that if the origin is well down along the lateral wall of the duodenum there would be more resistance to the escape of fluid than would be the case if the opening were situated on the anterior wall. Either a right or left sided opening would have a tendency to a valve-like effect. But no matter where the opening the fact remains that a duodenal fistula greatly excites the stomach to activity. The intestinal law of Bayliss Starling states that stimuli applied to the duodenum produce a muscular excitation in oral direction and a muscular relaxation in aboral direction. Barsony and Hortobaggy also showed that experimental duodenal fistula greatly increased the muscular activity of the stomach. This was shown graphically in their experiments.

The prognosis of duodenal fistula is always grave. The duodenum has its own succus entericus and also receives the bile, the gastric contents, and the powerful pancreatic secretions. A fistula therefore, causes loss of intestinal juices and all foods and fluids ingested. It is like turning off a mill race suddenly. Inanition dehydration and exhaustion comes on with extreme rapidity. The introduction of fluids rectally, intravenously, and by hypodermoclysis control

TABLE I.—GENERAL DATA, VARIOUS TREATMENTS, AND FINAL RESULTS

Surgeon Date	Diagnosis	Operation	Type of Drainage	Time of symptoms of lesion	Type of treatment	Length of life after treatment was instituted	Final result
Cramer 1895	Perforated duodenal ulcer	None	?	?	Conservative	1 month	Dead

	(2) Cholecystitis	Cholecystectomy	Drainage	5 days	1/10 normal HCL, lactase milk for buffer solution	9 days	Cured

the situation only partially. The toxic intestinal contents are undoubtedly absorbed along the fistulous tract. Studies of intestinal obstruction have shown that the pancreatic juice is very toxic—much more so than the contents of the cæcum.

This toxæmia has been very well described by Haden and Orr, Potter, and Walters. They stated that it was the result of rapid dehydration, due to the large volume of fluids lost and to the rapid depletion of chlorides. These factors caused an increasing alkalemia characterized by decreasing concentration of blood chlorides and progressive increase of blood urea. Walters concluded that the main cause of the toxæmia was the loss of the protective action of the chlorides of the digestive juices, which were discharged through the fistula. He thought that this loss turned the tide of neutrality of the blood toward alkalinity. He stated further that any toxic state is accompanied by increasing blood urea, due in some cases to the production of a nephritis which prevents the elimination of urea. At times it may be due to an

abnormal amount of urea formed from the breaking down of body tissues. Potter stated that the toxæmia associated with duodenal and fecal fistula is practically the same as that associated with intestinal obstruction.

As shown in Tables II and III the treatment of duodenal fistula has a mortality of 35.8 per cent. However separating the two major types of treatment, surgery has a mortality of 50 per cent, while the conservative treatment has a mortality of only 27.7 per cent. W J Mayo closed one case of posterior fistula successfully while Cameron cited five failures in six attempts. The toxæmia present in these patients is so severe that if operative procedures are resorted to before they at least have partially recovered, a fatal outcome is almost a certainty. Of the surgical procedures, simple closure, jejunostomy and enterostomy, carries the least mortality. Posterior gastro-enterostomy together with simple closure or combined with pyloric occlusion shows 7 deaths to 6 successful outcomes. Posterior

TABLE III.—RESULTS OF VARIOUS TYPES OF SURGERY PERFORMED ON DUODENAL FISTULA

Kind of operation	Cases	Deaths
1. Simple suture	5	4
2. Jejunostomy	3	4
3. Enterostomy	0	1
4. Gastro-enterostomy and suture	1	3
5. Gastro-enterostomy and Beck's paste	1	0
6. Gastro-enterostomy and pyloric occlusion	5	4
Totals	15	15
Per cent	50	50
Grand total of 30 cases treated by surgery		

gastro-enterostomy with pyloric occlusion was first practiced by Blegg and has proved successful in stopping the discharge at once. Jejunostomy is a great aid in stopping the discharge and is not nearly so dangerous. Direct closure of the fistula has been tried many times but the sutures usually fail to hold and the fistula recurs.

Einborn (11) employed the use of the duodenal tube in 2 cases successfully. In one of his cases the tryptic action was very marked. The tube was introduced *per os* and was kept in place for 2 days. It supplied food and water in abundance at small risk and lessened the discharge markedly. However the duodenal tube can not be used in cases of pyloric obstruction and in cases of resections of the stomach of the Billroth II type.

A constipating diet has been advocated. It is given with the idea of solidifying the intestinal contents and thereby lessening the flow of fluid through the fistula. Boiled milk has been used for the same reason. However the nausea and vomiting associated with the toxemia oftentimes renders any kind of feeding difficult. Rectal feeding is of some help but usually the time of healing is too long and the body weight can not be kept up. Oral administration of opium has been given to lessen the peristaltic action of the bowels.

Attempts have been made to dilute the trypsin. Cheever used a continuous stream of water to which had been added an alkali. He stated that the results on the fistula were good but that he had to discontinue its use because of irritation to the skin. Palmer also diluted the discharge with water to which he had added an alkali. There are other numerous references in the literature to attempts of healing the fistula by increasing the alkalinity of the discharges. Perhaps the minds of these workers were influenced by the fact that gastric ulcers heal under alkaline therapy.

Continuous suction was first used by Jones and Williams. Cameron used continuous suction on a case in 1923 with good results and Lahey used this method in 1924. It has certain very definite

advantages. The wound is kept fairly dry and this lessens the irritation in the wound and in the fistulous tract very much. The patients are much more comfortable locally. However, the loss of intestinal fluids is just as great as before. The toxemia, being dependent on the loss of chlorides and a beginning alkalosis, would probably not be influenced very much. The method is of value in cases in which the fluid loss is moderate and the toxemia of mild degree. The general condition of Cameron's case was good at all times and the fluid loss moderate.

It remained for Caryl Potter in 1927, to introduce a marked improvement in the conservative treatment of duodenal fistula. He first acidified the discharge by adding one-tenth normal hydrochloric acid in a continuous stream deep into the fistula. He then packed the wound with gauze which he kept soaked with a mixture of olive oil and beef extract. In other words, he first attempted to inactivate the trypsin by acidification and, then, supplied a buffer solution on which the bile could act without attacking the living tissues. There was also protein in the buffer solution to neutralize whatever trypsin might not have been acidified by the hydrochloric acid and thus rendered inactive. By these means he was able to stop the digestive action of the discharges at once and gave the fistula a chance to heal. He supplied fluids and dextrose abundantly as well as nutrient enemata. By these means the toxemia and the starvation were held in abeyance while the fistula healed. In 1929, he reported 9 cases which had been treated with this method with no deaths. This is the largest and the most successful series of cases treated by any one method.

Warnhaw and Hoffman, in 1930, treated a case successfully using Potter's method with a slight variation in buffer solution. They used a 10 per cent solution of Witte's peptone instead of Potter's mixture of beef juice and olive oil. They stated that they preferred the peptone solution

because of its greater ease of preparation. They also named three other solutions that might be used: egg albumen, protein milk powder and French gine.

In my 2 cases, the trypsin was acidified and thus rendered inactive by allowing one tenth normal hydrochloric acid to run deep into the fistula by means of a catheter. The wound was then kept packed with gauze which contained within it a second catheter supplying the gauze with the huffer solution, according to the arrangement of Warshaw and Hoffman. Each catheter ran back to a container, one for the hydrochloric acid and one for the buffer solution. The buffer solution used was whole lactone milk and this proved very satisfactory. It was prepared as follows. Whole milk was taken and re-pasteurized. Then this milk was cultured with stock culture of *Bacillus acidophilus* and kept warm for 6 hours, when it was quite thick. It was then placed in the container and used as a buffer. It was determined to try this after reading the work of Charles E. North on the beneficial action of lactic acid bacteria in the treatment of chronic fistula. The effect of the treatment was noticed immediately. The digestion of the tissues stopped at once and the pain ceased. The wound started to granulate. The fluid loss became less and less. The toxemia, which had been increasing rapidly, seemed to have improved almost over night. The two fistulas healed in 14 days and 3 weeks respectively. This treatment was supported by milk and egg enemas and by large amounts of fluid by the intravenous route as well as by hypodermoclysis.

SUMMARY AND CONCLUSIONS

An analysis of the 96 cases of external duodenal fistula reported in this paper shows that in 30 cases the fistulas followed operations on the gall bladder, in 22 cases operations for perforated duodenal ulcer in 8 cases after nephrectomy, in 8 cases after resections of the stomach for malignancy, in 7 cases after operation, for acute appendicitis with obstruction in 6 cases after rupture of the duodenum, and in 7 cases from other causes. Sixty five patients were treated conservatively with a mortality of 27.7 per cent and 30 patients were treated by surgery with a mortality of 50 per cent. The mortality for the whole group including all types of treatment, was 35.8 per cent.

In view of these statistics, it is seen that the prognosis of duodenal fistula is grave. The prognosis is most favorable when the fistula follows cholecystectomy when it is 26.7 per cent. Fistulas

following nephrectomies have had the highest mortality in this series, namely 80 per cent. Those following ruptured duodenal ulcer come next with a mortality of 50 per cent.

The statistics gathered seem to show that surgery in duodenal fistula has had its best results when used either very early or else very late. Conservative methods have had the best results. Potter's treatment, namely rendering the trypsin inactive by acidifying it by one-tenth normal hydrochloric acid and supplying huffer solutions containing fats and proteins has so far had perfect results. It seems that this treatment will become the treatment of choice.

Numerous buffer solutions have been used and have proved their value. Such solutions should contain fat and protein. A new buffer solution is offered to the profession namely whole milk thickened by the addition of *Bacillus acidophilus*. It was easily prepared and was used with complete success in my 2 cases.

REPORT OF CASES

CASE 1. Mrs. M. O., a white woman aged 45 years, had been well until she suddenly developed severe abdominal pain. Her family physician thought she was suffering from constipation and prescribed castor oil and enemas. She was seen by me 36 hours afterward and was then extremely sick. Her temperature was 104.5 degrees, pulse 120, respiration 36. The abdomen was distended rigid and very tender throughout. She was vomiting fecal material. A mass could be palpated in the region of the lower right rectus and the cul-de-sac was tender and boggy. A pre-operative diagnosis of acute appendicitis, probably ruptured was made.

At operation a ruptured gangrenous appendix was found. The pus cavity extended from the hepatic flexure to the pelvis. The small bowel was very much distended and it was evident that there was obstruction present. The appendix was removed without purse string suture and the cavity drained. An enterostomy was performed on the presenting loop of bowel, a No. 26F catheter being used. The abdomen was then closed with drainage.

The convalescence was rather stormy for the first 4 days, then quieted down, and the patient seemed to get along very well. Considerable pus drained from the wound and gas and fecal material drained from the enterostomy tube. The bowels moved and the enterostomy tube was removed. Then, on the thirteenth day after operation, the wound was wet and very tender. The patient complained of a burning sensation in the wound. The dressings were stained yellow and had an acid odor. In 18 hours the whole wound had broken open and had almost doubled in size in 24 hours. The patient was very toxic and at the end of 24 hours was semi-stuporous. The amount of liquid coming from the fistula was so copious that the dressings had to be changed every 15 minutes. It was determined to use Potter's treatment and the wound was dressed accordingly. The beef juice and olive oil mixture used by Potter was found to be rather difficult to prepare so whole lactone milk was substituted. This was whole milk which was thickened by infecting it with *Bacillus acidophilus*. The treatment was found to be very effective. In a very short time the pain in the wound had stopped. Soon thereafter the slough had loosened and

healthy granulation appeared, and healing went on quite rapidly. The amount of the discharge grew less and the fistula had closed 11 days after this treatment was instituted. The treatment was supported by milk and egg enemias, glucose intra-venously and hypodermoclysis of normal saline. The normal saline seemed especially effective in counteracting the toxemia, which was extreme in this case.

CASE 2. Mr. S. N., a white man aged 51 years, had had stomach trouble for about 15 years, which had been diagnosed chronic cholecystitis. The attacks of pain had been very severe, requiring at times grain doses of morphine for relief. The present attack had lasted about 8 hours and the pain had been continuous. He had also nausea and vomiting. The bowels had moved shortly after the attack had started.

The temperature was found to be 103.5 degrees, pulse 120, and respiration 30. The abdomen was extremely tender and rigid and the patient had a peritonitic feces. A diagnosis of acute abdomen, with possibly a gangrenous gall bladder, was made.

At operation the gall bladder was found to be acutely inflamed, and a stone was protruding from the common duct. On account of the severe inflammation present, it was thought best to drain the gall bladder. Soft rubber drains were put down to the common bile duct, after the rent had been wiped up and covered with a piece of omentum. The abdomen was then closed with this drainage in place.

The temperature during the first few days after operation was quite high and the patient was quite toxic. However, the bowels moved and he was getting along fairly well, everything considered. The drains outside the gall bladder were removed on the fifth day when it was noticed that there was some yellow fluid exuding from the wound. The patient complained of an itching and burning sensation in the wound. The next day the skin around the wound was excoriated and some fatty slough was present. The discharge was alkaline in reaction. A diagnosis of duodenal fistula was made and Potter's treatment instituted with whole lactose milk as a buffer solution. Atropine sulphate was given hypodermically every 6 hours in 1/200 grain doses. Supportive treatment of egg and milk enemias were given as well as normal saline intravenously and by hypodermoclysis. The fistula looked better after the first 24 hours and healed uneventfully in 19 days. The amount of discharge in this case was not so large as in Case 1 but it was copious.

TABLE V.—ASSOCIATED FRACTURES IN OTHER BONES

Sex	Age	Site of fracture in femur	Complicating fractures
M	40	Right junction middle and lower thirds	Head left skull
M	22	Junction middle and lower thirds	Lower third skull
M	50	Left suprascapular	Left radius and ulna
F	68	Junction middle and lower thirds	Right ulna
F	30	Left junction upper and middle thirds	Ascending nasal process, both sides
F	70	Left neck	Right left ulna
M	26	Right junction upper and middle thirds	Both bones right forearm
M	7	Right middle third	Left humerus
M	5	Median condyle	Tubercle and spine of ulna
F		Lower third	Middle of shaft of tibia and fibula
F	7	Left neck	Right radius
F	70	Junction lower and middle thirds	Skull
F		Left junction upper and middle thirds	Right (tibia and fibula) lower third (compound)
F		Left neck	Surgical neck left humerus
F	17	Right neck	Ribs
M	40	Junction middle and lower thirds	Left external maxillary
M	60	Right middle third	Crowning injury to 3, 4 and 5 fingers left hand (superficial) and left leg (superficial)
M	7	Right upper and middle thirds	Right clavicle
M	9	Right junction middle and lower thirds	Left tibia and left radius
M		Right suprascapular	Right scapula
M		Left junction upper and middle thirds	Right clavicle

OPEN REDUCTIONS AND MECHANICAL FIXATION

Twenty two (7 per cent) of the cases had some type of operative procedure performed for the fracture of the femur. Table VIII gives the list of these cases and the operative procedure.

Table VIIIA enumerates the cases of fracture of the neck of the femur which were fixed with screws by Denegre Martin's method.

Cases 13, 14, 15, 16 and 17 enumerated in Table VIII were from our wards. Only 79 (25.6 per cent) cases of fractures of the femur studied in this investigation were treated on our own service. Cases 13 and 15 were both compound fractures. Case 15 was the only instance in which Russell's method used by us in treatment of

TABLE VI.—CASES IN WHICH THERE WERE FRACTURES OF BOTH FEMURS

Sex	Age	Site of fracture in femur	Other complicating fractures
F	74	Both femurs middle third	Left humerus
F	7	Both femurs middle third	
F		Both femurs multiple fractures	
M	9	Both femurs junction middle and lower thirds	
M	7	Both femurs middle thirds	Radius
M	6	Both femurs—right junction upper and middle thirds; left middle third	
M	2	Both femurs—left lower and middle thirds (compound); right middle third	

TABLE VII.—COMPOUND FRACTURES OF FEMUR

Sex	Age	Site of fracture in femur
M	30	Left lower third shaft
M	5	Right middle third
M	5	Left middle third
M	23	Right middle third
M	60	Right middle third (also had crowning injury to left leg (superficial) and three fingers left hand (superficial))
M	21	Right junction upper and middle thirds
M	30	Left middle third (shaft)
M	20	Junction middle and lower thirds
M		Left junction middle and lower thirds—also two right femur
M		Right humerus
M		Greater trochanter (gunshot)

fracture of the shaft of the femur did not give a satisfactory result. (See end-results of fracture of the shaft.)

FRACTURES IN CHILDREN

Fractures of the femur in children are not uncommon. Eighty five (27.6 per cent) of the patients were under 13 years of age. Fractures of the femur in children almost invariably occur in the middle third of the shaft. In 76 (89 per cent) of the 85 patients under 13 years of age the fracture was in the middle third of the shaft. Various methods were used in treating these 85 patients. Overhead traction was commonly used when the child was very young. Russell's method was also frequently employed. Reduction and immobilization in plaster and Buck's extension were also employed in some instances.

TABLE VIII.—OPEN REDUCTION AND MECHANICAL FIXATION

Sex	Age	Site of fracture	Operative procedure	Ultimate result
1 M	6	Left middle third shaft	Open reduction	Perfect result
2 M	10	Right middle third shaft	Open reduction	Unknown
3 M	13	Middle third shaft	Open reduction	On distal end—union with shortening
4 M	3	Middle third shaft	Open reduction	Perfect
5 M	12	Shaft middle third	Former open reduction and fixation with plate. Plate removed	Unknown
6 F	60	Middle third shaft	Open reduction	Pneumonia—death
7 F	35	Middle third shaft	Fixed with Lane plate	On distal end—angulation
8 F	20	Middle third shaft	Open reduction	Infection—amputation
9 F	3	Middle third shaft	Fixed with Lane plate	Death. Cause not stated
10 F	43	Middle third shaft	Fixed with Lane plate	Union with shortening
11 F	17	Right shaft (left femur also)	Fixed with steel plate	Alignment good but stiffness right knee
12 M	5	Lower third shaft	Fixed with Lane plate	Perfect
13 M	20	Left shaft middle third	Fixed with metal band	Died. Cause not stated
14 M	13	Epiphyseal separation head	Reduction and suspension in Rowe's apparatus later wedge osteotomy	Unknown
15 M	1	Middle third shaft	Open reduction after failure to secure reduction by Russell's method	Unknown
16 M	5	Old fracture non-union middle third	Bone graft from tibia	Union
17 M	30	Lower third shaft	Lane plate	Union. Plate removed

This case was operated upon in another hospital

TABLE VIII.—DENFEGRE MARTIN FIXATION OF FRACTURE OF FEMORAL NECK

Sex	Age	Site of fracture	Operative procedure	Ultimate result
18 F	76	Right neck	Fixation with 2 screws	Union—shortening stiffness limp
19 F	66	Right neck	Fixation with 2 screws	Slight shortening. Leg stiff at times
20 F	36	Left neck	Fixed with screws	On distal end no union but good position with screws holding
21 F	60	Right neck	Fixed with screws	Non-union. Later head was removed and trochanter placed lower on shaft
22 M	32	Left neck	Fixed with screws	On distal end screws in good position

The result in children is almost always good regardless of the method used. We were able to follow up 28 cases of fracture of the femur in children under 13 years of age. Twenty three of these received a perfect result with no shortening, no weakness, no limp or residual of any kind. Of the 5 remaining, one has shortening and a limp, 3 patients report limping but have no shortening. One of these was a patient in whom there was a fracture in each femur, one of which was compound. This patient still has a draining sinus. One patient reported a limp, weakness of the knee and occasional stiffness with pain. Union was good without shortening.

MORTALITY

There were 22 hospital deaths, a mortality rate of 7.14 per cent. Pneumonia accounted for 10 of these deaths and possibly an eleventh. Disorientation and delirium in the aged resulted in three deaths. Fractured skull and cardiac failure in an asthenic man, uremia, and pulmonary embolism (questionable) accounted for one death each. The cause was not determined in four instances. There were 8 cases of intertrochanteric and six cases of fracture of the neck, among the 22 patients who died. This high death rate in cases with fractures of the neck and intertrochanteric region of the femur may be accounted

Fig. 1 left. In the lateral view the normal femur is bowed convexly forward.

Fig. 2 The triangle formed by the femur.

for by the advanced age of the patients in this group. The mortality rate in this series for intertrochanteric fractures is 14.5 per cent and for fractures of the neck of the femur is 10.9 per cent.

ANATOMICAL CONSIDERATION

In viewing the femur from the standpoint of normal contour, one is impressed with several striking points in its conformity. In the lateral view it is obvious that the normal femur is bowed convexly forward (Fig. 1). It is important to preserve this bow because if it is decreased or increased, it will result in the weight bearing line of force falling either posterior or anterior to its normal position in the foot. Viewing the femur anteroposteriorly the shaft again is bowed slightly with the concavity inward. When the individual is standing erect or lying supine with the heels together the shaft of the femur passes downward and inward from the greater trochanter and each femur may be regarded as part of a side of an isosceles triangle whose base is formed by an imaginary line between the trochanters and whose apex is at the intersection of lines projected below the knee in the direction of the shaft of the femur (Fig. 2). The neck of the femur usually joins the shaft at an angle of about 125 degrees. Decrease

in the angle results in a varus deformity with the effect of shortening of the femur and tilting of the pelvis toward the affected side to compensate for the deformity.

Whatever may be said for the contention that the ultimate end in the treatment of fractures is perfect functional result, the proximal aim in the treatment must be directed toward attaining a perfect anatomical result and by this a perfect functional result may be obtained. In fractures of the femur as in other bones of the body it is most desirable to have perfect apposition of fragments without angulation or shortening. By careful attention to detail and repeated checks on the alignment, we have found that this can be obtained very often indeed.

Muscles play a very important part in position of fragments in fractures of the femur gravity is no less important rôle. These two forces must be satisfied to obtain and maintain correct apposition and alignment of fragments. The usual displacement varies considerably depending on the level of the fracture. The displacement at different levels is more or less characteristic in fact, almost constant, with the necessary exceptions to justify the generality. When such is the case, it is due to more constant forces such as gravity and muscle tone and not to the extreme variable—the direction of the fracturing force.

When the fracture is in the neck of the femur the upper fragment is still attached by the ligamentum teres and the vacuum force of the acetabulum. The muscles running from the pelvis to the leg exert a shortening action while the external rotators with the force of gravity combine to carry the trochanter back and externally rotate the shaft. The same forces act in a similar manner on the lower fragment when there is an unimpacted intertrochanteric fracture. Here the capsule of the joint may also assist in holding the upper fragment in position.

If the fracture detaches the lesser trochanter this fragment may be displaced upward and forward by the iliopsoas. If the greater trochanter is broken off the gluteus medius and minimus, piriformis, gemelli, and obturator internus tend to displace it upward and backward.

In a peritrochanteric fracture, one passing transversely across the shaft between the two trochanters, the upper fragment is abducted and externally rotated while in a subtrochanteric fracture, the additional action of the iliopsoas on the upper fragment tends further to rotate it externally and flex it. In fractures in this region as in fractures at other levels across the bone upward displacement of the lower fragment is prone to

Fig. 3 Russell's method (From Russell, Brit. J. Surg. 1924 li 491)

occur due to the action of the muscles bridging the line of fracture. In securing alignment in per trochanteric and subtrochanteric fractures and fractures of the upper part of the upper third of the femur we believe that the lower fragment must be brought in line with the prereduction position of the upper fragment, i.e. into abduction whereas we do not believe that the lower fragment should be brought in the line of the prereduction position of the upper fragment if it is abducted in fractures in the lower part of the upper third the middle third or the upper part of the lower third of the shaft as we shall show.

In fractures of the shaft the lower fragment is almost constantly displaced posteriorly and upward with relation to the upper fragment and this is partially due to the action of gravity, partially to the tone of the gastrocnemius and popliteus and plantaris muscles flexing the lower fragment on the leg while the muscles bridging the site of fracture produce shortening. Moreover the adductor muscles are of the greatest importance in fractures of the shaft. The strong adductors tend to displace the fragments inward and they exert a more decided effect on the lower fragment since in the upper fragment adduction is opposed by the attached abductors. The adductor longus pulling up on the adductor tubercle tends to shorten the distance between the inner condyle and the pubic ramus. Abductors tend to abduct the upper fragment and thus an angulation with the convexity outward is often produced es-

pecially when the fracture is in the middle of the shaft. To overcome this angulation and to secure sagittal alignment, it is practically and even theoretically incorrect to carry the lower fragment into the prereduction line of the upper fragment, i.e. abduction. On the contrary the leg and lower fragment must be carried into adduction to relax the muscles which are producing the deformity. In a number of cases we have proved this repeatedly to our satisfaction that to correct external angulation of the femur in fractures of the shaft, the leg must be carried into adduction. Abduction only increases deformity. This sagittal alignment is easy to correct and maintain it is only shortening and posterior displacement of lower fragment which offer any difficulty.

In supracondylar fractures the lower fragment is flexed on the lower leg and upwardly displaced. Here gravity again and the gastrocnemius, popliteus, and plantaris each play a part in producing the posterior displacement. Muscles bridging the fracture effect the shortening. T or Y fractures into the knee joint are in effect supracondylar fractures but with the added complication of involvement of the joint and some times of separation of the condyles.

Fractures of single condyles may or may not be attended with displacement. Here muscles play less a rôle and the resulting displacement is largely the result of the fracturing force.

In epiphyseal separation at the lower epiphysis of the femur, the lower fragment is generally

Fig. 4. Modified Russell's method. The upper band is added to correct posterior displacement of the lower fragment.

anteriorly displaced and is flexed on the lower leg. Why the anterior displacement occurs is hard to explain, but so frequently was this lesion produced by a particular force—e.g. a boy getting his leg caught in the spokes of a wagon—that it became known as a cart wheel fracture and in absence of a better explanation, the fairly constant displacement may be attributed to the particular fracturing force.

METHODS OF TREATMENT

In this series various methods of treatment have been used. In the other fracture services of Charity Hospital the routine differs from the methods used in our wards. We shall however outline only the routine and the methods used in our service. Seventy-nine of the 308 cases reported in this article were treated in our wards. Anatomically these 79 fractures were divided as itemized in Table IX.

Modification of Russell's method in treating fractures of the shaft of the femur. In 1924, Russell of Melbourne described his method of treating fractures of the femur. We believe that this is the method of choice in treating fractures of the upper middle, and lower thirds of the shaft of the femur above the supracondylar region and below the subtrochanteric region. The method is intended to rest the muscles in their most accustomed position and by a combined pull on the knee and the lower leg to exert a force on the lower fragment of the femur in the normal line of the shaft (Fig. 3). A bath towel is placed under the popliteal space. To suspend the leg at the knee by this towel, a rope passes up and around a pulley A from which pulley a perpendicular dropped

would fall just below the tubercle of the tibia. Thence the rope passes around pulley B on the foot of the bed and back and around pulley C which is attached to a spreader separating lateral strips of adhesive applied to the sides of the lower leg. Then the rope passes back and around pulley D which is just below pulley B on the foot of the bed. A weight of 8 pounds (for adults) is fastened to the end of the rope. Russell emphasized the necessity of putting the leg into a position which is most natural for the muscles. He recommended the use of a pillow under the knee and the thigh to counteract posterior displacement of the lower fragment.

The only difficulty encountered was the tendency to persistent displacement of the lower fragment and one of us instituted the use of the upper band shown in Figure 4 to overcome this. This band is made of canvas and is separated from the skin of the thigh by cotton. It is suspended on either end by hooks on a 2 by 2 inch piece of wood the length of which is the width of the canvas. From the center of this strip of wood, a rope passes up and cephalad around a pulley and 10 pounds of weight are placed on the end of the rope. This last pulley should be placed so that the pull is perpendicular to the thigh.

We use Blake's foottrap to prevent foot drop. As far as rotation is concerned it is hardly necessary, for as Russell has said the towel under the popliteal space prevents this undesirable displacement.

To secure alignment in the anteroposterior view when the fracture is in the middle or lower third of the shaft, the leg is carried into adduction across the midline. This invariably has the desired effect and one should not be beguiled, when the upper fragment is in more abduction than the lower into attempting to bring the fragments into alignment by further abducting the lower leg. It seems paradoxical but correction here is obtained by bringing the lower fragment away from the line of the upper, i.e., to adduct the whole leg. This re-

Major Brachman.

laxes the adductor muscles which produce the deformity. When the fracture is in the upper part of the upper third of the shaft, i.e. almost in the subtrochanteric region, the leg must be abducted. Here the abductors have control of the upper fragment and the lower fragment must be brought into the prerotation line of the upper fragment.

It is desirable to institute immediate treatment in fractures of the femur. Examination should be done at once, an X-ray should be taken immediately and when the nature of the injury has been ascertained to be a fracture of the shaft of the femur and Russell's is the method selected for treating the leg should immediately be suspended in the apparatus. Morphine may be given but an anesthetic is not necessary. We have found that when delay is encountered some difficulty may be had in overcoming shortening and displacement. Shock does not contra indicate the application of the apparatus. Occasionally we have found it necessary to use more than 10 pounds on the lower hook up for a few days especially if the individual is very obese or very muscular. This weight must be reduced after correct position is obtained otherwise overextension may result and persistent overextension is to be avoided.

Repeated X-ray examinations are necessary, especially during the time perfect alignment is being secured. At the end of 4 days the fragments should be in perfect alignment but this sometimes means several adjustments of the apparatus to secure changes in position.

We keep our adult patients in this form of traction about 8 weeks, adolescents about 6 weeks. Toward the latter part of this period, the patient is measured for a Thomas walking caliper brace, which is applied immediately when the traction is removed. The patients wear the brace day and night for 1 month they take it off at night but continue to wear it when walking until from 5 to 6 months have elapsed from the time of the injury. They should remove the shoe daily, wash the foot, and put on a clean pair of socks. They are instructed to keep the knee hinge locked when they are walking and to open it each time they sit down. Moreover, they are instructed to sit on a table each day and work their leg with a muscle exerciser attached in order to mobilize the knee (Fig. 5).

Fractures of the shaft The technique we use has secured excellent results in our hands. In this series there were 31 cases of fracture of the upper, middle, or lower thirds of the shaft of the femur admitted to our service. One was a compound fracture on which an open reduction was done and the fragments were fixed with a Lane plate. Sub-

Fig. 5 A method of mobilizing the stiff knee after fracture of the femur. The dotted outline represents stiffness in extension.

sequently the plate had to be removed. The end result is not known. One was an old fracture of the shaft with non union. A bone graft was done and union resulted. Three of the patients transferred to other hospitals and were thus not treated entirely by us. One of these patients was treated by Russell's method in the other hospital. The result was unsatisfactory and an open operation was done. One patient 80 years of age had a compound fracture and an open operation was done immediately. This patient died. The 25 remaining were treated by the modified Russell method described herein. Two died. One, a patient 68 years old developed diarrhea and delirium and died and one aged 71 years died from a cause recorded as bronchitis. In none of the remaining 23 cases was it necessary to do an open operation. We have been able to follow up 9 of the 23. 7 of the 9 obtained a perfect result with no limp, no shortening, no stiffness and no weakness. Another wrote that he had a perfect result with no shortening, no stiffness, but he also stated that the muscles of the affected leg were a little weaker than of the other leg. He attributed this to disuse and said the strength of the limb

Fig. 6 Modified Russell's method used in treating intertrochanteric fractures of the femur. The leg is abducted and internally rotated.

was improving. The ninth patient replied that his result was not exactly perfect, that his leg was strong and he did not limp, but that he had some stiffness of the knee and the affected limb was about one inch shorter than normal. An X-ray picture taken before dismissal from the hospital showed good position with callus.

Fractures of the neck of the femur. Whitman's method has probably given the highest percentage of good results in the treatment of fractures of the neck of the femur. We have used a method modified from Russell's traction in the treatment of these fractures. So far we have not employed it in a sufficient number of cases to report on its efficiency.¹ The application of the Russell apparatus in treating fractures of the neck of the femur makes the patient far more comfortable than if he is encumbered with a cast. The apparatus is applied in the usual manner but the leg is carried into marked abduction by swinging the lower pulleys out (Fig. 6). The leg also is rotated internally by an adhesive band which is started on the lateral aspect of the leg and runs

up and in and around the leg. It is faced with another piece of adhesive where it comes in contact with the posterior aspect of the limb and from this adhesive a rope passes out and around a pulley. Six pounds are attached to the end of the rope. It is essential to attend diligently to the adhesive straps and replace them with fresh ones at the first signs of slipping.

In the elderly individual, we screw the fragments together with two wood screws after the method described by Denegre Martin. The necessity of getting the elderly patient out of bed is paramount. Approximating the fragments with wood screws is a relatively simple operative procedure and may be done under local analgesia with little discomfort to the patient. The operation does not expose the fracture or open the joint. Two drill holes are made in the external surface of the femur just beneath the greater trochanter. The drills, just a little larger than the unthreaded shank of the wood screw, are directed toward the head through the medullary portion of the neck of the femur. They only drill through the cortex. The screws may be pushed up to the head of the femur without resistance. They grip the detached head and with free rotation of the unthreaded

Since this paper was submitted for publication we have used this method in 4 cases and non-union resulted in each instance. From our experience we would condemn the method in the treatment of fractures of the neck of the femur.

portions of the shank in the drill hole the screws approximate the head to the distal fragment (Fig 7). If the patient is not too sick we perform the operation within 24 hours after admission. We have used this method recently in middle aged individuals with excellent results. They are permitted out of bed in 3 to 5 days but are not allowed unsupported weight bearing on the affected limb until union is complete.

Intertrochanteric fractures of the femur Intertrochanteric fractures are closely related to fractures of the neck of the femur. The prognosis as regards union is better in intertrochanteric than in fractures of the neck of the femur. Intertrochanteric fractures are extracapsular which makes a decided difference due in great part we believe to the fact that the fracture line is not bathed with synovial fluid. Synovial fluid seems to interfere with union—a factor which we are attempting to prove experimentally in dogs.

In intertrochanteric fractures we use the same methods given for fracture of the neck of the femur. We have had enough experience to say that Russell's apparatus yields excellent results (Figs. 8 and 9), and at the same time keeps the patient comfortable. The leg must be abducted and internally rotated. Martin's method is also of decided value in the treatment of intertrochanteric fractures and as many of these patients are old, we sometimes use it.

Pertrochanteric fractures of the femur In the pertrochanteric fracture of the femur the upper fragment is generally markedly abducted and externally rotated. Russell's method is applicable in the treatment but the lower fragment must be brought in line with the upper and therefore the limb is carried into abduction and is externally rotated by lateral skin traction applied in a manner analogous but in an opposite direction to that used in securing internal rotation in fractures of the neck of the femur.

Subtrochanteric fractures In addition to being abducted and externally rotated as in pertrochanteric fractures the upper fragment in a subtrochanteric fracture is under the additional influence of the iliopectus muscle and may be markedly flexed. Russell's apparatus is still applicable in these cases but the pulleys at the foot of the bed should be elevated to produce flexion of the hip. In treating this fracture however we prefer to use a Steinmann pin Kirschner wire or calipers at the lower end of the femur to obtain skeletal traction.

Fractures of the greater and lesser trochanters When the greater trochanter is fractured, there may or may not be displacement. If displacement

Fig. 7 The use of wood screws to approximate and fix the fragments in fracture of the neck of the femur. Denegre Martin's method.

is not present it is sufficient to put the patient at rest immobilizing the leg for 6 weeks. Suspended traction is much more comfortable and just as efficient as immobilization in a cast. When separation is present it is generally characterized by upward and backward displacement of the trochanter and the limb is put in a position of abduction external rotation and flexion at the hip. Here again we prefer suspended traction with the Russell apparatus to immobilization in a cast.

When the lesser trochanter is fractured it may or may not be separated from the shaft. If separation is not present immobilization for a period of time sufficient to permit union is all that is necessary. When separation is present, it is characterized by forward and upward displacement of the trochanter by the iliopectus. Approximation of the fragments can be best secured by flexing and externally rotating the thigh and the limb is immobilized in this position by skeletal traction or by a plaster spica extending from the nipple line to and including the foot.

Epiphyseal separations of the femur Separation of the epiphyses is fortunately rare. When separation of the upper epiphysis occurs it is of immediate effect comparable to the fracture of the neck of the femur. However the remote effects differ because of the age of the patient. It is essential to secure exact reduction. This is attempted under anesthesia and if successful, the limb is maintained in abduction and internal rotation by the use of Russell's apparatus applied in the manner described for fractures of the neck

Fig. 8. Intertrochanteric fracture on admission in Thomas splint.

of the femur. The apparatus is removed after 6 weeks. The youth is allowed to bear weight unsupported after 6 to 8 weeks. Open reduction is to be resorted to if success is not achieved by the closed method. Replacement of the conical upper end of the diaphysis in the concavity of the upper epiphysis is the end in view. Excision of the upper epiphysis is reserved for long standing cases in which traumatic arthritis has developed and a satisfactory functional result otherwise seems impossible.

When the lower epiphysis is separated from the shaft, immediate reduction under anesthesia should be accomplished. The limb is immobilized in a plaster cast in the position of flexion at the knee. After 3 weeks, the cast is bivalved and daily gentle motion is begun. After 6 weeks, the patient may be permitted supported weight bearing.

Supracondylar fractures of the femur. We have used Russell's apparatus in treatment of supracondylar fractures of the femur and have found the method unsatisfactory in these fractures. Here there is marked posterior displacement of the short lower fragment. It is flexed on the lower leg. Russell's apparatus does not permit the degree of flexion of the knee necessary. In these cases to secure proper alignment of the fragments. Too frequently posterior displacement of the lower fragment persisted when we used Russell's method. Therefore we have discarded this method and are using skeletal traction with satisfactory results. The method is shown in diagram in Figure 10. Traction is obtained by

Fig. 9. Union Intertrochanteric fracture in good position. Same case as shown in Figure 8 after treatment by modified Russell's method (Fig. 6).

passing a Steinmann pin through the tibia just posterior to the crest and just below the tubercle. A well padded double inclined plane is placed under the leg with an obtuse apex angle of about 115 degrees. The boards are so arranged that the apex presses up on the lower fragment. From the horseshoe attached to the Steinmann pin in the crest of the tibia a rope passes down and over a pulley on the foot of the bed. This pulley must be at such an elevation that it is below the level of a line projected from the shaft of the femur. In other words, the pull is so directed that the posteriorly displaced lower fragment is pressed up by the apex of the double inclined plane. In adults, 25 pounds for 36 to 48 hours are necessary to secure reduction then the weight is reduced to 15 pounds to maintain the position. The patient is maintained in this apparatus until mild union is obtained (5 to 6 weeks) and then Russell's apparatus is substituted and the patient remains in suspended traction for an additional 3 or 4 weeks. The after treatment is similar to that used in fractures of the shaft of the femur.

Fractures of the lower end of the femur into the knee joint. Fractures of the lower end of the femur into the knee joint are closely allied to supracondylar fractures of the femur. If there is marked separation of the condyles, we attempt to overcome this by use of the Boehler screw clamp. If this is not successful, a wood screw is used to approximate the fragments. The injury is then treated as a supracondylar fracture. If the frac-

FIG. 10. Method used in treating supracondylar fracture of the femur. The line of traction is below a line projected from the femur and the apex of the doubly inclined plane presses up on the lower fragment.

ture is complicated by hemorrhage into the knee the bloody fluid is aspirated and the joint is lavaged with normal saline. This is repeated as often as is deemed necessary.

Fracture of a single condyle. In fractures of the condyles there is no displacement of the fragments. Fixation in a plaster cast is an adequate method of treatment. Here synovial fluid we believe is prone to delay union and no non-supported weight bearing is permitted for 4 to 6 months. When there is displacement of the fragments, reduction may be accomplished by manipulation of the fragments when the patient is under anesthesia but if this is not successful longitudinal traction on the leg with lateral bands to correct varus or valgus or open reduction and fixation with a wood screw is resorted to.

END-RESULTS

It is to be remembered in reading these results that the patients were treated by many different men using a variety of methods.

It was very difficult for us to follow the class of patients reported in this paper. They are the poorest people of the city and state, not infrequently uneducated, frequently unintelligent, and often they change their addresses. Consequently, as would be expected, the percentage of those we were able to follow to determine the end results is low. We sent out questionnaires to all those patients who were dismissed from the hospital. We asked if they had a perfect result or if they had limp, weakness, stiffness, shortening, union or non-union, and also how long it took them to get over the disability resulting from the fracture. We received 84 replies. Twenty-eight of these were from patients who were under 13 years of age at the time they were admitted to the hospital.

As already stated the middle of the shaft was the part usually affected in children. Twenty-three (82 per cent) of the 28 replies received from the children showed that the child had a perfect result with no residual of any kind whatsoever. The 5 remaining were partially disabled. It is remarkable what powers of repair and compensation are ready in youth to overcome the injury. One of these children had union with overlapping and shortening of a centimeter to a centimeter and a half at the time of dismissal and now has a perfect result with no residual of any kind. In the growing child the shortened bone may grow faster than that of the opposite leg so that the asymmetry is overcome.

From patients over 12 years of age at the time of the injury we received 56 replies. These are tabulated in Table V. In computing the results we considered as totally disabled those patients who were confined to bed or who had still to use a brace or crutches or both as partially disabled patients who could walk but who had some residual, limp, stiffness, shortening, weakness, etc. and as perfect results, only those patients who had absolutely no remaining evidence of the former fracture.

Supracondylar fractures and subtrochanteric fractures show the greatest percentage of imperfect results. Replies from 4 patients with supracondylar fractures and one with supracondylar T fracture show that 2 of the 5 are totally disabled, 2 are partially disabled and only 1 had a perfect result.

Both of the 2 patients with subtrochanteric fractures who replied had imperfect results with limp and shortening.

Only 3 (23 per cent) of 13 patients with fractures of the neck of the femur had a perfect result.

TABLE V.—RESULTS OF FRACTURES OF THE FEMUR IN PATIENTS OVER TWELVE YEARS OF AGE

Location of fracture	Replies	Perfect results	Imperfect results	Totally disabled	Back-lame	Partially disabled	Patients not healed					
							Patients having lump	Patients having weakness	Patients having stiffness	Patients having non-union	Patients having shortening	Nerve paralysis
Neck of femur	5	3		2		2	20	0	5	1	3	
Intertrochanteric	14					3	6		3	1	7	
Subtrochanteric												
Upper third shaft												
Middle third shaft	9		6			6	6		4			
Lower third shaft												
Separately hit			3								3	
Separately hit T												
Single condyle												
Epiphyseal separation												
Unknown												
Total	38		14	7		8	7	7		5	11	

Five (38 per cent) are totally disabled and 5 (38 per cent) are partially disabled. Four (30.7 per cent) report non union. One patient with fracture of the neck of the femur died after leaving the hospital. This case is not included in the computations of end results.

Intertrochanteric fractures show a higher percentage of good results. Four (28.6 per cent) of 14 patients had a perfect result. Two (14 per cent) are totally disabled. Eight (57 per cent) are partially disabled.

Twenty-one patients with fractures of the shaft of the femur responded. One of these had a fracture in the upper third, one had a fracture in the lower third of the shaft. Both of these patients had a perfect result. The remaining 19 had fractures in the middle third of the shaft of the femur. Of these 21 patients 13 (62 per cent) had perfect results, none is totally disabled 8 (38 per cent) are partially disabled.

SUMMARY

Three hundred and eight cases of fracture of the femur received treatment in the wards of Charity Hospital, New Orleans, from June 1 1929 to May 31 1931. One hundred and ninety-two of the patients were males, 115 were females (1 67.1) and the sex could not be determined from the record of one. Seventy-nine of the patients were on the author's service.

The first decade of life was the decade most often affected there being 70 cases in our series. Thirty-six per cent of the patients were under 20 41.88 per cent were 50 years or older.

The shaft of the femur especially of the middle third is the most common site of fracture in the first and second decades of life the intertrochanteric portion and the neck are the sites more commonly affected after 50 years of age.

Although there were fewer females than males in the entire series, there were proportionately more women than men with fracture of the neck of the femur and with intertrochanteric fractures.

Nine per cent of the cases were complicated by fractures in other bones. Two and twenty-seven hundredths per cent of the cases had fractures in both femora.

In 3.6 per cent of the cases the fracture of the femur was compound.

Nerve injury was uncommon. It occurred once but was the result of the treatment instead of the fracture.

Fracture of the femur in children occurs almost always in the middle third of the shaft. The results were almost always excellent, in spite of a variety of methods used.

In 22 of the 308 cases of fracture of the femur some sort of operative procedure was done.

The mortality rate for the 308 cases was 7.14 per cent for intertrochanteric fractures alone 14.5 per cent and for fractures of the neck of the femur 10.9 per cent.

The methods we prefer are briefly described. In treating fractures of the shaft of the femur Russell's method with slight additions is our choice. In treating fractures of the intertrochanteric region, we also use a modification of Russell's method.

Eighty-four replies were received from the questionnaires sent to the patients. Twenty-eight replies were from children under 13 years of age at the time of their admission to the hospital; 23 or 82 per cent, of these received perfect results. Fifty-six replies were received from patients over 12 years of age at the time of their admission to the hospital. Those with fractures of the shaft of the femur show the best results (62 per cent perfect). Patients having fracture of the neck of the femur showed 23 per cent perfect results; 36 per cent are totally disabled and 38 per cent are partially disabled. Thirty and seven tenths per

cent have non union. Twenty-eight per cent of 14 patients with intertrochanteric fractures had perfect results. Fifty-seven per cent are partially disabled and 14 per cent are totally disabled. Fifty per cent of 5 patients with supracondylar fractures have persistent disability.

RENAL COMPLICATIONS OF BILIARY TRACT INFECTIONS

WILLARD BARTLETT Jr., M.D. St. Louis

IN 1928 the occurrence of acute nephritis with suppression of urine as a complication of severe biliary infection was forcibly called to our attention (Case 1). Since that time we have customarily estimated all cases of gall bladder disease from the standpoint of renal function. Meanwhile we have seen renal failure in 5 more patients (Cases 2 3 4 6 12) and have found a similar case history (Case 5) in our records of less recent date. The occurrence of so grave a renal complication in 6 of these 7 cases of a total of 56 patients with disease of the biliary tract under the care of my father and myself since Case 1 is certainly not a common experience in the practice of most surgeons. It is an indication of the fact that we at least, have to deal with very sick individuals, particularly during times of economic stress (2). The fact is that singularly few clinicians have concerned themselves with the possibility of renal failure in biliary infection whereas the chances for permanent damage to the liver pancreas and heart are fairly generally appreciated. Judd reported before the Section on General Surgery of the American Medical Association in 1935 an incidence of circulatory system disease over 50 per cent higher among patients with surgical diseases of the biliary tract than was the incidence for the age group according to the statistics of life insurance companies.

The majority of the few cases reported has been in the German literature. Clairmont and Haberer in 1912 presented 5 cases of renal failure occurring after operations on the biliary system 2 patients recovered. The presentation of the individual cases is so incomplete that a critical evaluation of them is difficult. Pre-operative urine findings were normal in 1 case and were indicative of kidney damage in another. The occurrence of jaundice was constant, but postoperative bile drainage is mentioned only once. All patients but one were subjected to cholecystectomy and choledochostomy under chloroform anesthesia. No indication is given of the competency of the circulation to maintain output of urine and it seems probable that in only 1 of the 3 fatal cases was suppression of urine due to nephritis. These authors did not succeed in producing anuria experimentally by ligation of the common duct in dogs though renal function by dye excretion sometimes showed im-

pairment. They concluded that the dog was not a useful experimental animal for the purpose, that anuria was always the result of parenchymatous damage in clinical cases of deep jaundice, and that surgeons might have to content themselves with cholecystectomy in such patients. In the same year Steinthal mentioned having seen such a case in which anuria developed on the fourth day after operation with death and characteristic autopsy findings of acute tubular degeneration. He considered that the anesthetic had been the precipitating factor there having been a latent renal insufficiency as a sequel of liver damage. Beck and Simon also reported having seen such cases die in uremia without operation. Staeheli in 1921 presented a case of his own, the patient dying anuric 3 days after cholecystectomy and choledochostomy there had been albumin in the urine before operation autopsy showed petechial hemorrhages into all the organs. He reviewed 3 of the cases of Clairmont and Haberer and a case of Kehrs, that of a 65 year old man, jaundiced who put out only 300 cubic centimeters of urine before death 4 days after cholecystectomy autopsy in this case showed only jaundice of all organs and arterio-sclerotic kidneys. Staeheli believed anuria to be the sum of many factors, most prominent of which are long duration of disease, infection, and deep jaundice. As for the effects of anesthetics, acute yellow atrophy of the liver was not found at autopsy in any of the cases reviewed and tubular necrosis (attributable to ether) in only one. In common with the previously quoted authors, he postulated a primary liver failure to detoxify substances which then damage the kidneys. He recommended careful functional tests of the kidneys before operation and urged early operation in acute severe cholecystitis to avoid renal complications. With the latter recommendation we must heartily disagree not simply for the reasons ordinarily urged, but because of evidence on this particular problem to be presented later. Abrahamson reported studies of renal function in 15 cases of jaundice due to various causes. None of his cases showed evidence of renal insufficiency (retention of nitrogen, salt, or water) and he felt that there was no significant change in the ability of his patients to excrete phenolsulphonephthalein. However he has included as normal one case in which

phenolsulphonephthalein excretion was 15 per cent, 2 in which it was 40 per cent one of 45 per cent (all in 2 hours after intramuscular injection) and one in which it was 40 per cent 2 hours after intravenous injection. Two of these patients had albumin and hyaline and granular casts in the urine. We do not consider these normal figures for phenolsulphonephthalein excretion in patients ranging from 23 to 50 years of age. It is our opinion that only 6 of his 15 patients showed really satisfactory dye excretion (60 per cent after intramuscular injection in 2, 60 per cent in 1 and 65 per cent in 3 after intravenous injection). Abrahamson urged quite properly that if dye excretion were low extensive operation was to be guarded against whereas a normal dye excretion offered some assurance that postoperative renal failure was unlikely to occur. With certain exceptions to be discussed later we quite agree to these proposals.

Wilensky and Colp made observations on the nitrogen partition of the blood in a large series of patients with biliary tract disease before and after operation in many cases some of these patients had evidence of nephritis though it is not made clear that any of them developed suppression of urine. The many observations in their last two papers are valuable material from which to draw conclusions though the conclusions to which we have come from a study of their figures differ widely from those of the authors. It is necessary to be specific in the discussion of these papers.

In the second paper Table I lists 56 cases of biliary tract diseases without jaundice or other complication and with normal blood nitrogen figures in all. Table II contains 13 "mild and moderate cases with jaundice but without demonstrable kidney involvement or other complication." Four cases have blood non-protein nitrogen values of 50 (3 cases), 62.9 and 71.7. The authors consider all of these as being within normal limits, apparently explaining the 2 last figures as being probably due to excessive nitrogenous intake in diet and conclude that varying degrees of jaundice "in the absence of kidney complications apparently do not influence the blood figures for non-protein nitrogen." Table III comprises 8 cases of mild and moderate biliary tract disease with or without mildest albuminuria and a minimal number of casts. Only one of these patients was jaundiced they are commented on as having no nitrogen change although 3 cases had non-protein nitrogen values of 49, 57.7 and 60.1. Table IV lists the findings in 9 cases with proved structural liver changes and it is the authors' comment that no particular change in blood nitrogen is noted. In the 2 patients who died, however non-protein nitrogen was 60 in one and uric acid was 5.3 in the other (non-protein nitrogen not determined). That the objections raised to the authors' deductions from pre-operative observations in the foregoing tables are valid is also borne out by the later behavior of the 8 patients (Cases 39, 49, 52, 75, 80, 81, 82, 83) in question when one follows them

in Tables V and VI of the second paper and in Table III of the third paper. In Cases 39, 52 and 83 apparently no operation was done. Case 49 has no postoperative determinations recorded, Cases 75, 80, 81 and 82 patients died after operation the first with a falling the third with a rising non-protein nitrogen and no postoperative determinations on the others. The 4 postoperative deaths among these 5 patients operated on occurred in patients who were not jaundiced, 3 of them being in acute attacks of gall stone disease and the fourth just after an acute exacerbation. Further figures of value are given in Table V of the second paper which deals with comparisons of pre-operative and postoperative blood nitrogen. A large increase occurred in 18 per cent of the cases reference to previous tables shows that this occurred, with one exception in cases operated on during an acute attack. The author reports 18 per cent of cases showing a decrease following operation (Cases 3, 34, 58, 57, 77) but in the first 3 cases the difference ranges from 0.8 to 2.4 milligrams per 100 cubic centimeters, approximating the limits of error of the method. Case 75 patient died although the non-protein nitrogen fell from 60 to 40. Case 77 patient a pre-operative non-protein nitrogen was 44.4, is variously listed as having a postoperative value of 33.3 in Table V and of 66.3 in Table VI where it appears with the cases classified as having both jaundice and nephritis.

There is in general much difficulty in reconciling the authors' comments in their text with the figures that appear in their tables. It is obvious that they have not recognized that retention of nitrogen occurs in some acute exacerbations of cholecystitis whether previous attacks have occurred or not, in the absence of jaundice and perhaps with normal urine. Their clinical observations however have impressed them with the importance of jaundice in causing renal lesions subsequent to hepatic cell damage and with the further effect of anaesthetics notably ether on an organism that is perhaps barely compensated previous to operation. We must disagree sharply with their observation that the simplicity or severity of the operation itself is of little consequence. Any important lowering of the alkaline reserve as a result of anaesthesia or operative trauma should seriously threaten a precarious liver and kidney function. The fact that of the 18 cases these authors classify as having been severely sick the 6 postoperative deaths and the 2 non-operative deaths occurred in acute cases should be ample indication of how poorly acutely sick patients withstand an added surgical insult.

Walters and Parham reported 2 patients dying of renal insufficiency, one before the other after operations for the relief of jaundice. They made the observation that following ether anaesthesia the blood nitrogen sometimes doubled in amount on the second and third postoperative days. They differentiated clearly between hepatic and renal insufficiency in these complicated cases

associated with the former there is abundant drainage of light colored bile containing small amounts of the bile pigments. Little change occurs in content or volume of the urine, and the blood urea remains persistently low.

It is not our purpose to go into the extensive literature on jaundice but a few outstanding facts pertinent to this discussion deserve mention. Rowntree, Snell, and Greene have made experimental investigations on obstructive jaundice in the most exhaustive detail. In the dog they did not observe suppression of urine and they found the blood nitrogen and its partition largely unchanged except for a terminal rise. uric acid did not appear. Bile pigments increased in value for 2 to 3 weeks then remained constant, due apparently to decreasing production; the initial increase was much more rapid when the gall bladder was removed at the time of the production of obstruction to the common bile duct. It was also found that ascites would appear when the animals were put on a protein diet and that it disappeared on resumption of a carbohydrate diet. It is not yet known definitely whether bile pigments or bile acids are the toxic factor in jaundice. It was the finding of Kling and Stewart that the injection of the pigment and not the salts of bile produced bradycardia and low blood pressure. The finding of bilirubin in the tissues does not necessarily mean of course that it is alone responsible for the parenchymatous damage observed. Haesler, Rous, and Brown found that the elimination of bile pigment during jaundice was markedly increased in the dog by flood diuresis with intravenous saline solution; the effect on the bile salts was unknown. No such effect was obtained by diuresis from water by mouth but these authors felt that accumulation of bile pigments might be diminished by such diuresis. The 'flood diuresis' was produced with saline solution introduced at such a rate as to be prohibitory in clinical use. They give a very thoughtful discussion of the significance of jaundiced epithelial cells in the urine sediment as evidence of renal injury. Wangensteen and his co-workers investigated the effect of repeated administration of ether and chloroform on output of phenol sulphonephthalein following experimental obstruction of the common bile duct in dogs. They found no evidence of impairment of kidney function nor did anuria develop, the urea nitrogen showed a terminal rise in only 2 of 16 dogs.

This raises the question of the interpretation of renal function tests in cases in which both kidney and liver damage is suspected. Hanner

and Whipple produced characteristic lesions of the liver by chloroform and phosphorus and in other cases produced obstructive jaundice in dogs. They then found in all cases an increase in phthalein excretion by the kidneys. They explained this by assuming that the 10 or 15 per cent of phthalein excreted through the bile by the healthy liver was shunted through the kidneys when liver function was grossly impaired. Their conclusion was that an abnormally high phthalein output in the presence of healthy kidneys should make one suspicious of serious impairment of liver function. For our own purposes, this adds to the value of the test. However the kidneys may be badly damaged in biliary infections with or without jaundice and without serious impairment of liver reserve, in our opinion, though our own clinical cases are not reported in such a way as to offer conclusive evidence in support of that opinion. Case 13 (aged 55 years) on the other hand with gross and microscopic evidence of hepatitis and phthalein excretion of 85 per cent in 1 hour after intravenous injection, probably is a case which fairly bears out the contention of Hanner and Whipple. In their paper they quoted Møller and Lungegaard as reporting a delay and decrease in phenolsulphonephthalein excretion in patients with hepatic disease; these cases are spoken of by Chabrier and Gamme in the paper as having had evidence of renal insufficiency. The subject must be regarded as being still controversial, especially in view of the fact that Hanner and Whipple's work is based on animal experimentation.

Wakefield, Power, and Keith have recently reported a large series of determinations of inorganic sulphates of the blood by an original volumetric method as a criterion of early renal insufficiency in chronic nephritis. Their cases are carefully and fully presented and merit close inspection. They found the sulphates increasing before a fall in phenolsulphonephthalein excretion. The closest correlation existed between the behavior of the sulphates, the "urea clearance" test of Van Slyke and the specific gravity of the urine as determined by the concentration-diuresis test of Volhard and Fahr. It will be interesting to see whether this method of sulphate determination will give us warning of impending kidney insufficiency in gravely sick patients with diseases of the biliary tract.

We have depended on examination of the urine determination of blood non-protein nitrogen, phthalein excretion, and various modifications of the Volhard and Fahr concentration-diuresis test in our estimations of the anatomical and func-

tional state of the kidneys it has not been possible to do them all or to repeat them at will in many of our patients. We have felt that more dependable results are obtained by injecting phthalein intravenously rather than intramuscularly since absorption rate must vary considerably from subcutaneous tissue fat and muscle into which the dye is variously deposited by different individuals. In clinical practice it is essential that voided specimens from women be uncontaminated every detail of the test indeed must be closely checked if one hopes to have valid records of progress. In the presence of jaundice, color matching with the standard is frequently impossible unless bile pigment be removed from the urine by one of the various methods. We find the ability to concentrate urine more satisfactory as a functional test and closely controlled research and experimental work by many workers has shown it to be of great value (10). We have not been interested in the ability of these patients to show diuresis since the cases that develop suppression of urine excrete urine of low specific gravity we have tested only their ability to concentrate therefore. Here again carrying out of a formal concentration test involving the withdrawal of fluids for a period of 15 hours or so is usually out of the question from a therapeutic point of view with patients who are acutely ill. In such cases the phthalein excretion is more widely useful. Until recently we have performed concentration tests with the patient on bed rest and on general hospital diet with or without meat, previous to the test. At 6:00 p.m. to 6:00 a.m. as one specimen from 6:00 a.m. to 9:00 a.m. all urine is collected as a second specimen the amount and specific gravity (by hydrometer) of both specimens is then measured. Patients whose kidneys we regard as being entirely normal do not ordinarily have a specific gravity below 1.015 or above 1.020 for the second specimen. This has seemed to us an inadequate method since the specific gravity of the combined specimens from 6:00 a.m. to 9:00 a.m. tells us nothing of the specific gravity of any of them unless the total quantity be quite small (less than 100 cubic centimeters) which is not usually the case. We have more recently therefore had the patient attempt to void at 7:00 a.m., 8:00 a.m. and 9:00 a.m., and catheterized for the final specimen if unable to void. These specimens are saved as separate ones. In this way we obtain one or two specimens of only an ounce or two for our final specimens and if such are not concentrated we can feel assured that some functional renal impairment exists.

Fig. 1. (Case 7) January 2, 1931 injection through Pessar catheter in gall bladder. Preliminary cholecystostomy November 20, 1930. Note normal cystic duct small patent common duct. Subsequent cholecystectomy without exploration common duct, was done March 24, 1931.

Quantities of urine less than one ounce are accurately diluted with water to an amount the specific gravity of which can be measured by the hydrometer. We have not had sufficient experience with this method to have set up an arbitrary standard of normal but it is our impression that one of the specimens after 6:00 a.m. should go above a specific gravity of 1.020 on this regimen with normal kidneys. We are aware of the many factors such as humidity, temperature and emotional states which influence the output of water through the kidneys and we attempt to take them into account as fully as possible in interpreting the results of these tests.

We are presenting the following 13 case records of patients with disease of the biliary tract that were or had once been amenable to surgery. Cases 1 to 6 are those who developed suppression of urine with other signs of nephritis. Case 12 probably belongs in this group also though his urinary output was not recorded. Cases 1, 6, 7, 8, 9 and 10 are submitted as those in whom a graded operation was planned. Cholecystostomy with maintenance of drainage for several months by Pessar catheter being the preliminary steps. Cases 11, 12 and 13 are

Fig. (Case 8 May 9, 93, incision through Pessar's incision in gall bladder. Preliminary cholecystostomy September 18, 1930. Note complete obstruction common duct dilatation cystic, common and intrahepatic tree. Subsequent cholecystectomy and exploration common duct May 14, 1931.

patients in whom no further operation than cholecystostomy was contemplated.

CASE 11. Mrs. M. S. age 57 years, admitted to the hospital, November 25, 1928 complaining chiefly of abdominal pain, jaundice, vomiting. First gastro-intestinal symptoms appeared 5 years previously with attacks of severe pain in right upper quadrant, vomiting, deep jaundice, clay colored stools. Patient could not get back to normal diet for 6 months. Health has been fair since, with intermittent attacks, mild pain, acholic stools, and constant belching and fullness after meals. She has not suffered a loss of weight. Present attack was of 3 weeks duration, no urine was voided for 24 hours before entrance.

Examination revealed an obese, elderly woman in considerable pain, nauseated, fairly alert, skin and sclera slightly yellow, obvious dehydration, heart slightly enlarged to left, regular sounds distant, blood pressure 160/70, pendulous abdomen, right rectus abdominis marked tenderness and infiltration, right upper quadrant a tender mass size of grapefruit and dull to percussion is palpable, liver not felt, temperature, 98 degrees, pulse 105, respiration, 18, white blood cells, 50,000, vomitus contained bile.

Patient was given hypodermoclysis of 1,600 cubic centimeters of saline on night of admission, morphine, and gastric lavage. She did not thereafter have enough pain to require morphine. At 7:00 a.m. November 26, she voided $\frac{1}{4}$ ounce for the first time in 36 hours. Hypodermoclysis was resumed and 50 per cent glucose was given intravenously. She was catheterized 4 hours later and there was obtained $\frac{1}{4}$ ounce of dark yellow urine, acid, showing a plus albumin, no bile, numerous white blood

cells and red blood cells, occasional coarsely granular casts, and numerous bacteria. During the rest of the day she voided $\frac{1}{4}$ cubic centimeters. Total output was $\frac{1}{4}$ cubic centimeters for the 30 hours since admission with an intake of 3,700 cubic centimeters by hypodermoclysis, 600 cubic centimeters of blood, and 500 cubic centimeters of 50 per cent glucose intravenously. At this time white blood corpuscle count was 52,000 with 86 per cent polymorphonuclear red blood corpuscles, 500,000, hemoglobin 98 per cent, non-protein nitrogen, 51, ketones index 25, blood pressure, 142/80. During that night she voided total of 270 cubic centimeters with an intake of 2,100 cubic centimeters under the skin. The following day she again received 50 per cent glucose intravenously and 2,900 cubic centimeters hypodermoclysis and the urinary output suddenly rose to 1,730 cubic centimeters in 24 hours. Urinalysis on November 26, showed 1 plus albumin acid, specific gravity, 1.005, numerous white blood corpuscles and red blood corpuscles, a moderate number of coarsely granular casts, acetone, negative. White blood corpuscle count had dropped to 3,000, temperature became normal, with pulse averaging 80. November 28, fluids in small amounts were started by mouth and the urinary output continued to exceed the fluid intake until December 4, there being considerable diuresis at night and there having been no demonstrable edema at any time. November 28 the non-protein nitrogen was 63, blood pressure, 140/70. December 1, non-protein nitrogen was 45; blood pressure, 210/90; and electrocardiogram showed normal curves. December 3, non-protein nitrogen was 44, blood pressure, 160/80. December 3, catheter urine specimen showed reaction, acid, specific gravity 1.005, trace albumin, a few white blood corpuscles, and bacteria. December 4, white blood corpuscles numbered 9,000. December 6, ketones index was 16. There was no nausea after December 5, but a persistent sensation of abdominal fullness and belching was noted.

Operation was done December 11. Nitrous oxide gas plus novocain infiltration and block anesthesia was used. An enormous gall bladder filled with thick black bile and stones was aspirated, sutured to peritoneum, and a large soft rubber tube inserted into the gall bladder for drainage; no exploration was attempted.

The postoperative course was uneventful except for considerable lagging of urinary output behind the fluid intake during the first 3 days. Patient was discharged December 20, 1928, with a small amount of seropurulent drainage around the tube. Bile drainage was prompt following operation and decreased in amount after the first few days, not exceeding 300 cubic centimeters each 24 hours during the final week in the hospital. During the first 3 weeks after discharge patient passed twelve stipes through the tube which came out 6 weeks after operation and was not replaced. Stools were of normal color at all times. There was a small but constant amount of drainage from the fistula, the belching and sensation of fullness disappeared and there were no pain, chills, or jaundice.

Patient was readmitted to the hospital June 18, 1930, having been for 1 week on a 1,000 calorie diet with thyroid, grain 1/80, daily. Reduction regimen continued for a week after entrance. Catheter urine showed reaction, acid, specific gravity, 1.021, slight trace of albumin, no occasional white blood corpuscles, hemoglobin, normal temperature, pulse, and respiration, normal blood pressure, 160/80.

Operation was done June 25, 1930. Nitrous oxide and novocain infiltration and block anesthesia were used. The abdomen was opened just lateral to the old scar; the gall bladder was moderately thickened. It was aspirated

Fig. 3. Case 10. February 2, 1931. Injection through Pezzer catheter in gall bladder. Preliminary cholecystotomy July 29, 1930. Common duct apparently normal, emptying promptly. Subsequent cholecystectomy not yet done (see text).

Fig. 4. Case 14. October 31, 1930, injection through T tube in common duct. Farcion stricture and choledochostomy December 10, 1929. Note persistent dilatation of common duct and intrahepatic radicals. T tube removed December 4, 1930.

and packed the ducts appeared normal in size and thick-
ness. Cholecystectomy was performed with drainage to
stump of cystic duct.

The postoperative course was entirely uneventful. The
urine output was good at all times. Patient was dis-
charged July 11, 1929. On April 3, 1932 she was re-
examined. Digestion has remained excellent, no pain or
jaundice, regained weight to 203 pounds during past
winter but has recently developed toxic adenoma thyroid
and diabetes mellitus and weight has fallen to 165 in the
past 4 months.

CASE 2. Mrs. M. B., aged 58 years was admitted
April 5, 1929. The chief complaint was jaundice with
continuous vomiting. Onset of jaundice 1 month ago
with mild pain in both upper abdominal quadrants,
nausea, and vomiting with increasing severity. Incon-
tinence of urine and feces, stuporous past 48 hours. Past
history was not obtained.

Examination revealed an obese elderly woman, deeply
jaundiced, stuporous, obviously dehydrated, marked fetor
oris, teeth poor, lungs entirely clear, heart rapid, regular,
size uncertain, sounds rather distant, no murmurs, blood
pressure, 105/52. The abdomen had no scars, both upper
quadrants and epigastrium were tender and spastic; the
liver was not palpable, no masses were felt, the pelvis
was not examined, no edema of extremities, temperature,
99.2 degrees, pulse 115, respiration, 24. The catheter
urine was dark brown, acid, specific gravity 1.009, 3 plus
albumin, bile, positive, moderate number red blood cells,
a few white blood cells and granular casts.

Immediate blood transfusion was given and intake main-
tained by hypodermoclysis of saline and 10 per cent glu-
cose intravenously. Small nasal tube was introduced into

the stomach and left there 150 cubic centimeters of orange
juice being inserted every 3 hours. Intake from entrance
for 20 hours, nasal tube 750 cubic centimeters, hypo-
dermoclysis, 2,800 cubic centimeters, intravenous 1,000
cubic centimeters, total, 4,550 cubic centimeters. Out-
put she vomited small amounts twice, urine was voided
involuntarily twice in very small amounts, per catheter
180 cubic centimeters, total? April 6, white blood cor-
puscles were 13,000, red blood corpuscles, 5,250,000,
hemoglobin, 100, non-protein nitrogen, 53, icterus index,
130, urine many red blood cells and 1 plus albumin
pulse 85, blood pressure 118/65. Patient was still stu-
porous. Twenty-four hour intake, mouth, 2,300 cubic
centimeters, hypodermoclysis, 3,600 cubic centimeters,
intravenous, 100 cubic centimeters (50 per cent glucose)
total 6,000 cubic centimeters. Output stomach syphon-
age 1,350 cubic centimeters, urine 610 cubic centimeters
per catheter, total 1,960 cubic centimeters. April 7, pa-
tient failed rapidly, temperature stayed normal and pulse
was under 100 until 2 hours before death at 6:50 p.m.
Marked edema developed around eyes and moist bronchial
rales appeared at 11:00 a.m., blood pressure 168/90 at this
time. No precordial friction rub was heard. Intake from
7:00 a.m. until 6:50 p.m., mouth, 340 cubic centimeters,
hypodermoclysis, 1,000 cubic centimeters, 50 per cent
glucose intravenously 50 cubic centimeters, total, 2,190
cubic centimeters. Output syphonage 1,425 cubic cen-
timeters, urine 250 cubic centimeters per catheter, total
1,675 cubic centimeters. Autopsy was performed im-
mediately following death. Moderately increasing bile
stained fluid was found in pericardium and peritoneum;
there were hemorrhages into the wall of the small in-
testine and cecum amounting almost to gangrene, the

Fig 5. Case 5. June 10, 1932 injection through T tube in common duct. Cholecystectomy and choledochotomy May 23, 1932. Note dilatation common duct and intrahepatic radicals, with prompt emptying though patient in Trendelenburg position.

appendix was densely fixed in old adhesions and contained one fecalith. The liver was rather small with dilated ducts, gall bladder hypodermic and adherent to stomach. Ramen of Winslow obliterated, no stone in common duct, a hard mass size of lemon in head of pancreas, right kidney weighed 75 grams, left a little less, surfaces smooth, capsules stripped easily, cut surfaces showed well defined cortex and medulla, petechial hemorrhages into renal pelvis, heart negative except for deep jaundice which all organs showed. All parenchymatous organs, stomach, duodenum, and pancreas were saved for microscopic examination but were misplaced and no report of them is available.

Case 3. Mrs. H. F. age 71 years, admitted December 14, 1931. Her chief complaint was jaundice and indigestion. Eight years ago she had had attacks of nausea, vomiting without pain or jaundice over a period of 2 months. Five years ago she had an attack of severe pain in the upper abdomen and chest radiating to back, lasting 3 days and associated with much nausea, nocturnal vomit or twice nightly for past year increasing to 4 or 5 times in past 6 months. Six months ago she had noted onset of weakness, but loss of less than 10 pounds, clay colored stools for 2 months, edema of legs to groins for 3 weeks, nausea and belching but no vomiting or pain, some palpitation past 3 weeks, no orthopnea or dyspnea. She was confined to bed for past 3 weeks without improvement. Very small doses of digitals were given for week before admission. The onset of jaundice has been so gradual that it cannot be definitely dated.

Examination revealed a stout elderly woman, alert, not in pain. The skin was a peculiar bronze, the sclera yellow; the heart was not enlarged, the apex impulse was some-

what diffuse, the sounds were clear, regular of good quality with no murmurs, an occasional extrasystole. Blood pressure was 140/75, the lungs were negative. The abdomen showed no scars, the wall was relaxed, the right lobe of the liver was felt 3 finger breadths below right costal margin, edge rounded, perhaps irregular, and slightly tender. The gall bladder was palpable, tender. No free fluid demonstrable. The back showed slightly pitting edema over lumbar and sacral regions. The pelvis and rectum were not examined. Pitting edema noted on both legs to knees. No varicos were noted in legs or abdominal wall. Temperature was 96.2 degrees; pulse, 82; respiration, 22. Catheter specimen of urine was acid, specific gravity 1.009, bile, positive; very occasional red blood corpuscles and cocci, hemoglobin 77 per cent, red blood cells 4,300,000, white blood corpuscles, 7,600, differential (Schilling)—eosin, 3, stab, 28 segmented, 42 lymphocytes, 22, large mononuclears, 5, leucocytes index, 60, van den Bergh, positive, direct reaction, stool, negative for bile and for occult blood. Intravenous iso-iodolom gave no gall-bladder shadow but there were characteristic shadows of stones in gall-bladder area. Forty-two per cent of the dye was retained in the blood 30 minutes after injection. Electrocardiogram showed T waves broad and flat in all leads and left axis deviation.

Impression. Obstructive jaundice due to (silent) stone in common duct or less likely pressure on common duct from carcinoma of gall bladder. The edema was thought to be due to myocardial failure with incomplete digitalis effect.

Patient was put on limited fluid intake with salt-free diet high in carbohydrate on December 1; the edema of the legs and back had almost completely disappeared and the liver was barely palpable. During this 24 hour period, however, she voided only 40 cubic centimeters. Fructure of digitals, 1 cubic centimeter every 4 hours, was started as a diuretic although the pulse was 80. December 17 patient was weak, drowsy, complaining of visual disturbance. Fifty per cent glucose was given intravenously with insulin and blood transfusion. Total intake was 1,500 cubic centimeters. Output urine was 170 cubic centimeters, and there was again considerable edema of the back. December 18, non-protein nitrogen was 47, leucocytes index, 75, catheter urine, acid, specific gravity 1.012, 2 plus albumin, bile positive, numerous white blood corpuscles, and bacteria. Intake 1,000 cubic centimeters. Output 410 cubic centimeters after cubic centimeter of alyrgan intravenously. December 19, 1 cubic centimeter alyrgan was given intravenously in 30 per cent glucose with insulin and repeated daily thereafter. Catheter urine showed reaction, acid, specific gravity 1.005, 3 plus albumin, bile positive, a few red blood corpuscles, and a moderate number of white blood corpuscles. Intake was 1,600 cubic centimeters. Output was 480 cubic centimeters. December 20, patient was quite drowsy, considerably weaker, edema legs and back was increasing, but no ascites or pulmonary edema were noted. Digitals was discontinued since the pulse remained about 70. As indwelling catheter was inserted in order to keep track of the urinary output as patient was beginning to void involuntarily. Stools were light brown for the first time and were faintly positive for bile, which was present thereafter until death. Leucocytes index was 110. Carbon dioxide combining power was 38.5 volume per cent; blood chlorides 310 milligrams. December 21, intake was 1,700 cubic centimeters, output 780 cubic centimeters. The urine was unchanged. Temperature, pulse, and respiration remained normal, blood pressure 110-60. December 22 patient was quite stuporous. Intake was 1,380 cubic centimeters, output was 560 cubic centimeters. The urine was acid,

specific gravity 1.005, 3 plus albumin, numerous red blood corpuscles, white blood corpuscles, and bacteria. December 23 patient expired.

Permission for autopsy limited to abdomen was obtained. The findings are to be reported in detail in another paper primary adenocarcinoma of the liver cells (malignant hepatoma) with small organoid metastases to the lungs, peritoneal fibrosis, chronic cholecystitis with cholelithiasis, marked dilatation of common duct with small fresh ulceration of mucosa (stone not found in duct or in intestine) small retention cysts in pancreas, slight necrosis of peri-pancreatic fat, chronic perisplenitis, cloudy swelling of the kidneys with deposit of albuminous material in the glomerular capsules and in the tubules marked jaundice of viscera. The heart was examined through an incision in the diaphragm. It was not grossly enlarged and the muscle was soft. There was a moderate amount of bile-stained fluid in both pleural cavities and a small amount in the peritoneal cavity.

CASE 4. Mr L. P. aged 53 years was admitted to the hospital April 3, 1932. Patient had been under observation as an ambulatory case until the night before entrance. The referring physician had studied him exhaustively a month previously with complete gastro intestinal and gall bladder X-rays, blood chemistry, electrocardiograms, etc. and a final diagnosis of cholecystitis with cholelithiasis had been made. The urine had then been normal and phenolsulphonphthalein excretion was 75 per cent in 4 hours after intravenous injection. There was a history of epigastric pain, abdominal fullness, and belching after meals, in spells, for about 10 years. Constant jaundice varying in degree had been present for 3 months before admission, clay colored stools for 1 month, swelling of abdomen (ascites) for 10 days, oedema of ankles for 4 days. On admission there was noted a deep jaundice of the skin and sclera. Patient was somewhat drowsy, lips and nails were cyanotic, audible moist rales were noted throughout bronchial tree. Percussion note was dull in lower axilla and posteriorly. The apex impulse was diffuse in fourth intercostal space, 5 centimeters to left of sternum, sounds faint and regular, no murmurs. The abdomen was distended, shifting dullness present in both flanks. There was slight tenderness in the right upper quadrant and epigastrium, no masses or viscera were palpable. Pitting oedema noted in lower anterior abdominal wall and back. The genitalia and rectum were negative. Pitting oedema noted in feet and ankles. Temperature was 100 degrees, pulse, 128, respiration, 24, blood pressure, 115/60. Catheter urine showed acid reaction, 3 plus albumin, bile positive, a few hyaline and granular casts, moderate number red blood cells, a few white blood cells and bacteria. Hemoglobin 65 per cent, red blood count 3,000,000, white blood count 8,000, differential (Schilling) basophils, 1; Y cells, 45; stab, 30; segment, 12; lymphocytes, 10; icterus index, 60.

In the first 36 hours, April 3 to 4, only 160 cubic centimeters of urine was passed with fluid intake of 2,000 cubic centimeters of 5 per cent glucose intravenously and a negligible amount by mouth and proctoclysis. When we first saw the patient on the morning of April 4 he was quite stuporous, physical findings had not changed since admission, blood pressure 118/60, pulse 124, respiration 24, and it was our impression that he had in addition to obstructive jaundice a nephritis which was responsible for his oedema rather than circulatory failure. Non-protein nitrogen was 68, uric acid 4.4. An attempt was made to start diuretics with salyrgan and 50 per cent glucose intravenously which were repeated 12 hours later. 450 cubic centimeters of blood was given as transfusion and oxygen started continuously by nasal catheter. Only 310 cubic centimeters were obtained before death which occurred on

the morning of April 5. Until shortly before death pulse remained around 120, respiration 24, temperature slightly subnormal. Permission for autopsy was refused.

CASE 5. Miss M. B. aged 61 years, admitted to hospital April 4, 1928. Her chief complaint was increasing jaundice and abdominal pain. The first attack of severe pain in the right upper quadrant of the abdomen occurred 14 years ago with bloating and fullness after meals. She had had several similar attacks of colic during the next 4 years, none for the past 10 years though indigestion continued. Two weeks ago she had a sharp attack of pain followed the next day by jaundice which has steadily increased with clay colored stools and considerable vomiting. No vomiting had been noted for past few days.

Examination revealed an obese elderly woman, deeply jaundiced, not in pain, quite nervous, belching frequently. The heart was slightly enlarged to left. The abdomen was quite tender under the right costal margin otherwise negative. The temperature varied from normal to 99.9 degrees, pulse varied from 68 to 110 with the temperature. April 5 hemoglobin was 85 per cent, white blood cells 6,000, clotting time 5 minutes, icterus index, 150, van den Bergh, immediate direct reaction, urine acid, specific gravity 1.015, faint trace albumin, bile positive, numerous leucocytes, a few hyaline and granular casts.

She was given intravenous glucose on admission. April 6 blood transfusion, calcium chloride was given intravenously on three successive days. She was put on a high carbohydrate diet. There was inconstant nausea, no vomiting, stools of normal color after April 6. Temperature came back to normal on April 8 and went up to 100 on April 10 and to 101 degrees on April 16. It was thereafter normal. April 13 icterus index by mouth gave an uncertain hazy shadow in gall-bladder region. Icterus index 150 on admission, 180 on April 7, 100 on April 10, and 60 on April 14. Non-protein nitrogen was 42 on April 7, April 16 white blood cells were 6,000, clotting time 4 1/2 minutes.

Operation was done April 21. Ether and novocain infiltration and block anesthesia were used. The gall bladder was cystic, the common ducts thickened, enlarged, and buried in dense adhesions. One mulberry pigment stone was found in the gall bladder. The common duct was opened, and careful exploration revealed no stone or obstruction. There was free passage into duodenum. A catheter was sutured into the hepatic duct. A drainage tube was sutured into the gall bladder in view of patient's age and rather poor condition. Penrose drain was inserted into the common duct. Pulse was 94 at conclusion of operation.

Postoperative course. Temperature was 103 degrees night of operation and 101 degrees the following morning. April 23, pulse suddenly went from 100 to 160. Heart action was regular. Blood pressure was 110/80, the pre-operative level, and there was a suggestion of pulsus alternans. Respiration was 24. Patient was digitalized on advice of consultant, with massive doses, and was then maintained on digitalis thereafter. Pulse returned to 90 that night and was usually between 80 and 90 thereafter. Bile drainage was immediate, averaging 600 cubic centimeters in 24 hours for 1 week. Stools were of normal color until eighth day after operation. April 29 they were continuously clay colored thereafter until death. A moderate amount of bile-stained drainage continued on the dressings but no digestion of skin occurred. Following operation water intake was maintained by mouth, 2,000 to 2,500 cubic centimeters daily. The urine on day after operation showed faint trace of albumin, specific gravity 1.024, and was normal microscopically. Urinary output declined steadily from 800 cubic centimeters in 24 hours to less than 100 cubic centimeters daily. This was not noticed

until April 26 when patient began to complain of urgency which responded to symptomatic treatment. April 26 specific gravity was 1.014, faint trace albumin, bile positive, numerous white blood cells, a few hyaline and granular casts. Fluid intake thereafter was peaked beyond 3,000 cubic centimeters daily and blood transfusion was given. The urine output fell to between 350 and 450 cubic centimeters daily however until death. April 25 temperature rose to 102 degrees, then gradually fell to subnormal where it remained until the day of death. April 30 non-protein nitrogen was 60 urine showed heavy trace of albumin, bile positive, a few red blood cells and white blood cells, and small bacilli. No further laboratory examinations are reported until death which occurred on May 6, 1938. Patient was restless and disoriented during the last week. Permission for autopsy refused.

CASE 6. Mrs. C. K., aged 63 years, was admitted to the hospital October 30, 1930. She had had an attack of nausea and vomiting one year ago with burning sensation in epigastrium lasting 3 days. She had suffered from fullness and belching after eating since then. Forty-eight hours ago burning pain in epigastrium and right upper quadrant recurred and vomiting of bile-stained fluid started. Pain was continuous, shifting 12 hours ago to right lower quadrant vomiting was intermittent. Stools were normal and daily during present illness. There were no cardiorespiratory or genito-urinary symptoms no chills or jaundice. She was given morphine by referring physician before she was sent 75 miles to hospital with diagnosis of acute appendicitis.

Examination revealed an obese, elderly woman mentally alert, but very tired in moderate pain skin and sclera normal, head and neck negative except for dry tongue—heart enlarged somewhat to left, sounds of good quality. A snoring, occasional extrasystole was noted. The lungs were slightly emphysematous. The right rectus muscle was in moderate spasm. There was marked respiratory inhibition. The liver edge was palpable 3 to 4 finger breadths below the rib margin on the right. Continuous with it there was a tender tense mass the size of a lemon extending to the level, and to the right of the umbilicus, and moving with respiration. Pelvic examination revealed no tenderness or induration on either side. Temperature was 98.4 degrees pulse, 86 and respiration, 20 blood pressure 140/85 white blood cells, 34,000. Catheter urine, showed acid reaction, 3 plus albumin, many hyaline and finely granular casts, occasional white blood cells, no organisms, non-protein nitrogen 37. A fat film of the abdomen showed clearly a gall-bladder shadow at site of the tender mass. Impression: empyema of gall bladder. Patient was put on penicillin treatment with nothing by mouth 3,000 cubic centimeters saline solution as hypodermoclysis, 1,000 cubic centimeters 10 per cent glucose intravenously in the 16 hours until the morning following admission. During this time she voided 150 cubic centimeters of urine. October 30, white blood cells were 25,300 temperature, 99.8 degrees pulse, 96 respiration, 22. Patient felt greatly rested.

Operation was done October 30. Nembutal, grains 3, was given intravenously pituitous oride and local infiltration and block anesthesia being used. Through a short, high right rectus incision the abdomen was opened. The peritoneal fluid was found to be bile-stained and greatly increased in amount. The gall bladder was freed from the omentum. It was the size of a small coconut, greatly thickened, and dark blue in color. It was lifted into incision and attached to fascia with Allis clamps and aspirated of thick blue green bile and many tiny stones. A Pezzer catheter was introduced, one plain gauze pack and two small iodoform packs were left in the wound

around the gall bladder to create adhesions. Closure to packs and tube, the clamps being left in place. A note was made on the operative chart that patient was to wear the Pezzer catheter for 6 months and then have a cholecystectomy. At end of operation pulse was 120, respiration, 25, blood pressure, 132/70. Blood transfusion was given immediately and penicillin treatment resumed for 24 hours. During this period with a total intake of 3,300 cubic centimeters the output of urine was 785 cubic centimeters. Temperature was 101.3 degrees, pulse, 100; and respiration, 25, the night of operation gradually returned to normal in the next 3 days. She was put on soft diet on the third day. There was immediate bile drainage, not exceeding 100 cubic centimeters per 24 hours. Stools were normal in color at all times. Gastric packs were removed at intervals until the twelfth day. Patient was to be allowed up on November 12, but that morning she developed a left-sided bronchial pneumonia of which she died November 21. Permission for autopsy refused.

CASE 7. Miss L. M., aged 37 years, was admitted to hospital November 13, 1930. Since appendectomy for ruptured appendix 6 years ago she has had spells of minor upper abdominal discomfort especially after eating raw fruit. Four weeks ago there was a sudden onset severe pain in the right upper quadrant and epigastrium, the pain radiating around the rib margin to the right scapula, there were considerable vomiting, fever, and onset of jaundice. Morphine was required to relieve pain. She vomited 3 to 5 times daily for 3 weeks, once daily since then. Jaundice gradually subsided, she had had no chills, uncertain as to acholic stools. The past history was negative except for scarlet fever and diphtheria when a child. Examination revealed a short, rather obese woman, not in pain, skin slightly yellow, sclera clear—head, neck, heart, and lungs negative. Blood pressure 135/85. There was an old low right rectus scar, healed by secondary intention, no distention or spasm, moderate tenderness in epigastrium and right upper quadrant slight inhibition, no masses or viscera palpable. Pelvis and rectum not examined. Temperature was 98 degrees, pulse, 88 and respiration, 18. Catheter urine showed acid reaction, specific gravity 1.014, faint trace of albumin, bile negative, sediment negative, hemoglobin 83 per cent; white blood cells 6,000 differential (Schilling) normal, ketone index 3.1. Impression: chronic cholecystitis with subsiding acute exacerbation, question of stone in common duct. November 14, phenolphthalein 540 cubic centimeters, 45 per cent in 2 hours (intramuscular). Because of history of definite changes in color of stool during first week of attack it was felt that her common duct would have to be explored. Because of her thick, peculiarly deep thorax and abdomen this promised to be very difficult. It was felt that her phenolphthalein-ketone correlation should improve before undertaking so radical a procedure.

November 15, urine concentration test 6 a.m. to 7 a.m. 2 cubic centimeters, specific gravity 1.0. 6 a.m. to 9 a.m. 17 cubic centimeters, specific gravity 1.008. Phenolphthalein 530 cubic centimeters, 37.5 per cent in 2 hours (intramuscular). November 16, phenolphthalein 630 cubic centimeters, 37.5 per cent in 2 hours (intramuscular). With this definite evidence that kidney function was far from normal we informed patient that she could either wait until kidney function improved with the risk of further attacks of colic in the meanwhile or have the cholecystectomy performed at once with subsequent cholecystectomy and exploration of common duct. She preferred the latter course.

Operation was done November 20. Phenadon, grains 15, was given preliminary to operation. Nitrous oxide plus local infiltration and block anesthesia were used.

Through a lateral right rectus incision the fundus of the gall bladder was brought into the wound and anchored with Allis clamps and a Pezzar catheter was inserted into it. Clamps were left in place for 48 hours.

Postoperative course was uneventful for 9 days. The urinary output good. Immediate bile drainage was from 100 to 300 cubic centimeters per 24 hours when it exceeded 200 cubic centimeters, it was injected into the rectum as retention enema, patient in chair on seventh day. On ninth day developed thrombophlebitis on left saphenous vein. This improved on the usual treatment. December 11, 1932, she was discharged. The incision was healed to the catheter. January 1, 1933, she was readmitted to have Pezzar changed. She has had two attacks of colic similar to those before operation but they were much less severe and without jaundice. The stools have remained normal in color. Temperature, pulse and respiration were normal. Blood pressure 120/80. Urine concentration test showed 6 p.m. to 6 a.m. 2 cubic centimeters specific gravity 1.002 6 a.m. to 9 a.m. 2 cubic centimeters specific gravity 1.014 Phenolsulphonphthalein output was 155 cubic centimeters, 47.5 per cent in 8 hours (intramuscular). Voided urine showed reaction alkaline, 1 plus albumin moderate number white blood cells, a few red blood cells. Lipidol injection into catheter showed no obstruction in the common duct and prompt emptying into duodenum. February 16 she was readmitted to have the Pezzar changed. She had had entire comfort until a week ago when the catheter began to slip out of the gall bladder and with partial blocking of fistula the gall bladder became tender red and there was a slight purulent discharge. Temperature pulse, and respiration were normal blood pressure was 120/80. The urine concentration test showed 6 p.m. to 6 a.m. 2 cubic centimeters, specific gravity 1.017 6 a.m. to 9 a.m. 2 cubic centimeters, specific gravity 1.013 Phenolsulphonphthalein 185 cubic centimeters, 42.5 per cent in 2 hours (intramuscular). Lipidol injection into catheter showed common duct patent and emptying promptly. March 18, 1933, she was readmitted for cholecystectomy having felt well in all respects except for occasional soreness about the tube. Lipidol injection gave results as before with no dilatation of hepatic or common ducts. March 20, concentration test showed 6 p.m. to 6 a.m., 535 cubic centimeters specific gravity 1.010 6 a.m. to 9 a.m. 60 cubic centimeters specific gravity 1.011 Phenolsulphonphthalein 720 cubic centimeters, 53 per cent in 2 hours (intramuscular). March 23, concentration test 6 p.m. to 6 a.m., 2 cubic centimeters specific gravity 1.000 6 a.m. to 9 a.m., 2 cubic centimeters specific gravity 1.002.

Operation was done March 24. Nitrous oxide gas and anesthesia was used with ethylene novocain block of abdominal wall. Through a right rectus incision between the midline and fistula the common and hepatic ducts were found to be normal in size and consistency. No stones were felt and the ducts were not opened. Gall bladder wall was 1 inch thick on the peritoneal aspect. It was removed and a small gauze pack partially surrounded by rubber was placed against the liver bed and brought out old fistula. After operation the urine output was satisfactory at all times, approximating the intake after the first 24 hours. The course was uneventful except for considerable purulent drainage from the sinus for several days after removal of packs and drains. No bile drainage was used. April 13 patient was allowed up. She elected to stay in the hospital until the sinus had completely granulated. April 26, 1933, she was discharged. March 30, 1933, she felt excellent was eating everything with good digestion until past December when she weighed 153 has since developed symptoms of thyrotoxicosis and has lost 10 pounds.

Pulse was 116 blood pressure 155/95. Patient refused to remain for complete examination but it is our impression that she has not only a toxic goiter but definite renal damage in view of high diastolic pressure.

CASE 8 Mrs D M aged 63 years, was admitted to hospital August 31, 1930. She had been entirely well until 1 month ago at which time there was an onset of severe pain in the right upper quadrant, radiating to back, and she became jaundiced had a sensation of fullness, she belched after meals and had pain which continued intermittently. She vomited several times with attack 3 days ago. The stools were frequently clay colored. Her past history was uneventful except for malaria 4 years ago. Her average weight was 120 pounds.

Examination revealed a moderately obese elderly woman in slight pain with slight jaundice of skin and sclera heart and lungs negative abdomen flabby fat positive inhibition moderate tenderness in right upper quadrant and epigastrium no masses or viscera were palpable extremities were negative weight 150 pounds. Temperature was 99.4 degrees pulse 88 and respiration, 22 September 3 red blood cells were 4,370,000 white blood cells, 9,400 hemoglobin 70 per cent differential normal icterus index, 12.1 non protein nitrogen, 30.9 September 3 temperature returned to normal and a glucose tolerance curve was normal no spilling of sugar. Urine concentration test was performed but the specimens were mislaid and no report was available. September 5 icterus index 10 catheter urine acid faint trace albumin bile positive a few red blood cells and white blood cells phenolsulphonphthalein 400 cubic centimeters, 75 per cent in 1 hour (intravenous). September 8 non protein nitrogen 38.4 icterus index 10.3 Patient's appetite was improving though she was still occasionally nauseated and her general strength was somewhat better. She no longer complained of intense weakness and prostration. She was started on thyroxin, grain 1/80, daily. September 16 calcium chloride 5 cubic centimeters of 10 per cent solution was given intravenously and repeated on the next 3 days.

Operation was done September 18. Morphine-atropine preparation nitrous oxide plus novocain infiltration and block anesthesia. Through a short, high, right rectus incision the gall bladder was exposed and found to be thick, small rather red and completely behind the liver. It was fixed to the upper angle of the wound with Allis clamps and aspirated. A Pezzar catheter was inserted into the gall bladder which was then fastened with Allis clamps to the fascia. Iodoform gauze was packed around the gall bladder and closure was made in layers around the pack and tube, clamps were left in place. Patient was returned to bed with a pulse of 94. After operation there was immediate bile drainage, highest temperature was 100 degrees the first night after operation. The urine output was satisfactory. On September 23 the clamps were removed. On September 26, patient was up in chair and the gauze pack was removed. On October 3 patient was discharged. The incision had healed except for a granulating area immediately around the Pezzar catheter. Bile drainage averaged only 5 to 3 ounces daily.

On October 15 weight was 154 pounds. Two stones passed through the tube. February 11, 1931, three stones were passed. March 15 stools had been normal in color since operation. The Pezzar was changed and Lipidol was injected for visualization of the biliary tree patient has recently had mild influenza. On May 18, patient was readmitted to hospital weight was 140 pounds, she having lost 10 pounds since influenza attack. Urine concentration test showed 6 p.m. to 6 a.m., 420 cubic centimeters, specific gravity 1.005 6 a.m. to 9 a.m., 180 cubic centimeters specific gravity 1.012 Phenolsulphonphthalein 390

cubic centimeters, 55 per cent in 2 hours (intramuscular); catheter urine was negative smear of bile showed no pos., numerous gram-negative bacilli, and gram-positive cocci. Lipiodol injection through Pessar showed obstruction of the common duct and outlined the biliary tree exceptionally well.

Operation was done May 14. Phenobarbital grains 15, preparation Nitrous oxide gas and ethylene were used for anesthesia. Through an incision 3 centimeters to right of the midline everything was found to be adherent to the gall bladder at its junction with the abdominal wall. The ducts were considerably thickened and greatly dilated. Three small pigment stones were removed from the pancreatic portion of the common duct, a probe then entered the duodenum easily. A T tube was sutured into the hepatic and common ducts and a greatly thickened gall bladder was removed. A Penrose drain was inserted suture line, brought out with the T-tube through the previous biliary fistula.

After operation, the highest temperature was 100 degrees on the first day. It returned to normal on fourth day. Urine output was good. There was immediate bile drainage of 400 cubic centimeters daily for two days after which it decreased to about 50 cubic centimeters per 24 hours. The stools were 1 normal color except one passed on the eighth day; patient was quite weak and apathetic for 4 days and was started on thyroid grain 1/60, daily. Patient was slow in regaining strength, p on fourteenth day. On June 3, 1931, at 11 a.m. discharged, 80th day. A moderate infection of the drainage tract subsided on 100 days.

July 7, 1931, the stools continued normal in color. We had been clamping off T-tube 1 pass few weeks without symptoms. The T tube was removed October 30, 1931. No symptoms whatever were noted. July 1, 1932, weight 60 pounds. Patient eats everything. She has no gastrointestinal symptoms, no pain, bowels move daily; her general health and strength are excellent.

Case 9. Mrs. C. C. aged 61 years, admitted to hospital Jan. 2, 1930. For 5 months she had attacks of paroxysmal pain in the right upper quadrant and epigastrium, with vomiting. She was jaundiced during most of the attack. Her last attack was 3 days before entrance to hospital, with chills and a temperature of 104 degrees. The pain subsided but there was persistent burning sensation in the region of the gall bladder. Her past history revealed that she had had an operation for cysts of the ovaries in 1903 following which the wound burst open and drained for 8 months. The wound reopened and following this she developed an incisional hernia. Operation for ruptured appendix was done in 1913.

Examination revealed a moderate degree of jaundice, heart and lungs negative. The abdominal wall was firm with two old healed incision scars and a small incisional hernia, the right rectus was spastic, there were marked inhibition and tenderness in the right upper quadrant. Temperature, pulse, and respiration were normal. Urinalysis revealed reaction, acid specific gravity 1.000, occasional white blood cell. She was put on a high carbohydrate intake and fluids were forced. July 7, icterus index was 6.8. July 5, cholecystostomy was performed under nitrous oxide gas plus novocain infiltration and block anesthesia, after 15 grains of phenobarbital was given by mouth. Through a very short incision a large catheter was sutured into the gall bladder.

The postoperative course was entirely smooth. The catheter came out of gall bladder on the first day after operation and was replaced by a Pessar (meshbroom) catheter. July 10, patient was up in a chair. July 13, she was discharged. July 30, tube came out followed by a small

facted stone. The tube was replaced and continuous drainage instituted. September 26, patient was feeling excellent eating everything; weighed 120 pounds. October 30, patient reported passing considerable bile at all times through tube, but much more since an attack of headache and a fever of 103 degrees a week previously. Stools are always clay colored, and there was occasional diarrhea. Sharp epigastric pain was present at times for past few weeks, the appetite was fairly good, she had no chills; weight was 120 pounds. November 2, non-protein nitrogen was 30, icterus index, 5 phenolsulphonphthalein 245 cubic centimeters, 60 per cent in 2 hours (intramuscular). November 15, patient was readmitted to hospital. Blood pressure was 130/78. The liver was not palpable. A Pessar catheter was placed in the fistula. The stools were usually acholic. She had been fed bile salts continuously since previous discharge. She started on thyroxine, grain 1/60, daily. Catheter urine showed reaction, acid, specific gravity 1.015 microscopically and chemically negative.

Operation was done November 18. Phenadren, grains 15, preparation was carried out. Nitrous oxide anesthesia was used. Through an incision high in the right rectus and close to midline, the gall bladder appeared little changed, no stones were found in the gall bladder or cystic duct, the common and hepatic ducts commonly dilated, with walls gray and thick, the common duct contained multiple pigment stones in its entire pancreatic portion. The stones were removed and the instruments readily passed into the duodenum. A large catheter was sutured into the hepatic duct, a Penrose to suture line in common duct, the wound was closed. Pulse was 78 at end of operation. The highest temperature after operation, 101 degrees on first night, normal after fourth day. Urinary output was good at all times. Bile drainage was immediate and averaged about 200 cubic centimeters for 24 hours, until the catheter came out of the hepatic duct on the eighth day after operation. Drainage through the Pessar catheter in the gall bladder was thereafter only about 75 cubic centimeters per 24 hours. December 1, up in chair. December 6, discharged with incision completely healed. There was no bile drainage around the Pessar catheter. The Pessar catheter was removed in March, 1932, after lipiodol injection had shown the common duct to be patent and emptying promptly into the duodenum. The fistula healed in about 10 days. May 19, 1931, patient weighed 125 pounds and excellent in every way. June 22, 1932, weight 123, digestion excellent, bowels moved daily without cathartic, eats everything; blood pressure 125/75; considers herself 100 per cent normal.

Case 10. Mrs. O. D. aged 49 years, was admitted to hospital July 26, 1930. For past 3 1/2 years she had had sensation of distention of abdomen and belching after meals, particularly after eating fat, occasional stabbing pain in right upper quadrant during this time. She had had intermittent pain during past month, no jaundice, stools of normal color.

Examination revealed the following: heart size cannot be made out, sounds regular, only fair quality; blood pressure 144/78, lungs negative, abdomen much flat; considerable epigastric tenderness and induration in right upper quadrant, lower quadrants negative, penis and rectum normal, weight 163 pounds. Voided urine was alkaline, specific gravity 1.003, few white blood cells and bacteria.

Operation was done July 30. Phenobarbital, grains 15, was given in divided doses as preparatory measure. Spinal anesthesia was used. Through a high right rectus incision a long, adherent, scarred appendix was removed. The gall bladder was found to be thick, gray, incompressible,

and filled with black bile, much mucus, and sand. Patient a condition on the table became unsatisfactory and it was thought unwise to perform cholecystectomy. Drainage of the gall bladder was therefore carried out with a Pezzar catheter.

Temperature went to 103 degrees on night of operation and to 103.4 degrees the following night, gradually returned to normal but rose to 99.4 degrees almost daily for 3 weeks. The incision healed cleanly. Patient allowed up on twelfth postoperative day. September 17 she was discharged weighing 145 pounds.

The subsequent course has been uneventful. February 11, 1931, she reported her digestion vastly improved, no pain or belching and sensation of fullness rare but drain age was averaging 5 ounces per 24 hours. She was instructed to clamp off the catheter continuously as long as no discomfort resulted. In July 1931 she described her condition as perfect and removal of the gall bladder was advised. January 6, 1932, she reported her digestion excellent, weight 165 pounds. She had been wearing the tube clamped off continuously for 6 months without symptoms. She was still deferring operation because of inability to meet hospital expenses and was to continue wearing the tube until she could arrange to re-enter the hospital for cholecystectomy.

CASE 11. Dr. F. S. aged 64 years, was admitted to hospital September 4, 1929. He had had a posterior gastroenterostomy in 1914 for duodenal ulcer with relief of pain but persistence of occasional attacks of nausea were relieved by induced vomiting of large amounts of bile stained fluid. Ten years ago he began having mild attacks of pain in the right upper quadrant with nausea and vomiting followed by tenderness in the upper abdomen for about a week. Attacks were precipitated by eating sweets, meat, or fried foods. One week ago he had a very severe attack of pain in the right upper quadrant and back and to relieve pain induced vomiting and took morphine. Temperature 103 degrees, he had no chills or jaundice and no abnormal stools.

Examination revealed weight 142 pounds. The head, neck, and chest were essentially normal for his age. There was a rather marked thickening of the peripheral vessels. Blood pressure was 150/86. The right upper quadrant was tender, the liver was palpable one to two finger breadths below the right costal margin, the edge was sharp and below there was marked positive infiltration. There was an old healed midline scar. Temperature was 99.6 degrees, pulse 90, respiration 22, white blood cells, 10,000, red blood cells 3,800,000, hemoglobin 85 per cent, van den Bergh, negative, icterus index 4.8, non protein nitrogen 25. Urine on September 6, acid, specific gravity 1020, microscopically and chemically negative. A transfusion of 500 cubic centimeters citrated blood was administered and patient was discharged on September 11 because of head cold which had been hanging on for several days. He was readmitted September 18 and he was operated upon the following day.

Phenobarbital grains 12 were given as a preliminary measure. Nitrous oxide gas plus novocain infiltration and block anesthesia were used. A large non faceted pigment stone was removed from the gall bladder the mucosa of which was grossly necrotic; the gall bladder was stuffed with a small loquiform pack in the hope of obliterating it. All ducts were grossly normal and were not explored. Patient vomited considerably and hiccupped for the first 3 days after operation. His highest temperature was 101 degrees, he sweated profusely and had very obviously had all the operating that he could have withstood. The course thereafter was smooth. The pus was removed from the gall bladder. A Pezzar catheter was

inserted in its place and the patient discharged on October 1 with the incision healed.

The Pezzar came out in about a week after discharge from the hospital and was not replaced. The fistula healed in 10 days. November 1930 his weight was 157 pounds. September 1931 his weight was 153 pounds. July 1932 his weight was 151. Patient has been working continuously as a general practitioner since 6 weeks after discharge from the hospital. About every 3 months he has an attack of mild pain in the right upper quadrant with nausea both of which are relieved by lavaging his own stomach from which he recovers large quantities of bile tinged fluid. He can still precipitate such attacks by eating too much meat, eggs, chocolate or milk or by getting quite tired. These attacks do not incapacitate him. He enjoys complete comfort otherwise and his strength is good. He considers himself 75 per cent normal.

CASE 12. Mr. J. F. aged 70 years, was admitted to the hospital September 17, 1930. He had had intermittent pain in the left upper quadrant and epigastrium for past 7 months without other symptoms. Five days ago he had begun to vomit almost everything he ate and had had a constant gnawing pain in the epigastrium. He had daily passage of normal stool, no jaundice.

Examination revealed a weak, exhausted elderly man in moderate pain. The head, neck, heart and lungs were normal for his age, no obvious dehydration. The abdomen was very tender in the right upper quadrant. There was marked inhibition on respiration. The epigastrium was less tender. The lower quadrants were negative. The genitalia and rectum were normal. The extremities were negative except for a rather marked thickening of the peripheral vessels. Temperature was 97.9 degrees, pulse, 84, respiration 20, blood pressure 120/86, differential (Schilling) count infectious type urine, acid, two plus albumin, numerous hyaline and granular casts, a few white blood cells.

Patient vomited at intervals for the first 4 days but was thereafter perfectly comfortable. Temperature remained normal. September 19, non protein nitrogen was 64.5, phenolsulphonphthalein no trace 1 hour (intramuscular). Test meal showed no free hydrochloric acid, positive for bile, negative for occult blood. Stools were of normal color and negative for blood. Gastro-intestinal and gall bladder series of films revealed a deformed gall bladder shadow with some pulling of the second portion of the duodenum toward the right. September 22, phenolsulphonphthalein 345 cubic centimeters, 24 per cent in 2 hours (intramuscular). Urinalysis showed specific gravity 1.005, microscopically a few organisms. September 30, phenolsulphonphthalein 375 cubic centimeters, 47.5 per cent in 2 hours (intravenous). Amount of urinary output during this pre-operative course was not recorded.

Operation was done October 3. Nitrous oxide gas, ethylene plus novocain infiltration and block anesthesia were used. The gall bladder was incompressible and adherent to the duodenum by extensive adhesions, the pylorus bound down but normal on palpation and inspection. Cholecystostomy was performed by the usual technique, drainage was carried out with a Pezzar catheter.

The postoperative course was entirely smooth and on October 13, patient was discharged. A report from his referring physician at the present time states that the patient wore the tube 8 months, had no pain, but occasional belching after meals, regained normal strength and weight. At the end of 8 months the tube broke off at the level of the skin and he entered another hospital as a clinic patient where the tube was removed and cholecystectomy was performed because it was felt that the gall bladder was non functioning. His present health is said to be good.

CASE 13. Mr. H. V., aged 53 years, was admitted to the hospital January 24, 1930. He complained that 20 years ago for a period of about 6 months he suffered fallens and dull discomfort in the right upper quadrant after eating meat: fried foods. He eliminated these foods from his diet and enjoyed fair comfort until 8 years ago when pain recurred and he was slightly jaundiced for 2 or 3 months and had clay colored stools. Indigestion persisted until 6 months ago when agonizing pain recurred with nausea and vomiting during which a left inguinal hernia appeared. Intermittent pain and great eructation had been present since this attack. His best weight was 230 pounds, fifteen years ago. His average weight is 125 to 128 present weight, 115 pounds.

Examination revealed a small, thin man looking older than his years. Skin and sclera clear, mouth foul, heart and lungs normal, blood pressure 120/70. The abdominal muscles were very lax and there was an obvious bulge in the right upper quadrant representing the liver which extended from the sixth intercostal space in the right midclavicular line to four finger breadths below the costal margin, edge rounded, quite tender. The gall bladder was not palpable. The lower quadrants were negative. The extremities were negative. The temperature, pulse, and respiration were normal, blood and urine normal, stools, normal, negative for occult blood. Phenolsulphophthalein output was 340 cubic centimeters, 85 per cent in 1 hour (intravenous). Electrocardiograms showed ventricular extrasystoles and left axis deviation. Gastro-intestinal X-rays showed the second portion of the duodenum pulled to the median line, the stomach emptying promptly and a redundant colon lying largely in the pelvis. He was given blood transfusion and 700 cubic centimeters 10 per cent calcium chloride intravenously on successive days before operation. Pre-operative diagnosis was chronic cholecystitis and chronic cholelithiasis, question biliary cirrhosis.

Operation was done in January 1931. Phenobarbital, grains 15 were given in preparation. Ethylene anesthesia was used. Through a right rectus incision the right lobe of the liver presented a rounded border of finely granular surface, grayish-red in color, no gross nodules. On the peritoneal surface of the ascending colon were several firm yellow nodules the size of BB shot, one of which was removed for biopsy. The gall bladder was enormously dilated, not adherent, thin walled, and incompressible. The pyloric end of the stump and transverse colon were attached firmly to the region of the common duct which could not be readily palpated. The spleen was smooth, somewhat enlarged. The gall bladder was aspirated of greenish, normal appearing bile and then a large soft rubber tube was inserted into it and transfused. A small wedge was taken from the liver edge for biopsy. A drainage tube was clamped for gradual decompression. The wound was closed about the tube. Pathological report of the nodule from the colon was vegetable fiber stalk with foreign body reaction and fibrous connective tissue encasing it. The section of liver showed moderate degree of pigmentation and low grade chronic inflammation and infiltration. Diagnosis: low grade chronic hepatitis.

Patient was returned to room with pulse 84. Decompression of the gall bladder was carried out by releasing 1 ounce of bile from the tube every hour for the first 24 hours. Continuous drainage was then allowed. The highest temperature was 101 degrees on first day after operation. It was normal after the fourth day. The patient, however, was extremely weak and we felt sure that more radical operation would probably have proved fatal. For the first 3 weeks, bile drainage varied from 450 to 1,200 cubic centimeters per 24 hours, averaging about

700 cubic centimeters. Bile salts were fed by mouth and the patient's condition gradually improved. On the tenth postoperative day he was given another blood transfusion on the twelfth day he was allowed up, on the fifteenth day the tube came out of the gall bladder and was replaced with a Pessar catheter and the bile drainage was less than 500 cubic centimeters per 24 hours at all times. February 23 he was discharged with instructions to replace all bile drainage as retention enema when it amounted to more than 200 cubic centimeters per 24 hours.

The Pessar came out one month later and as the drainage had greatly diminished in amount and stools had been of normal color at all times it was not replaced. The fistula closed in 30 days. July 5, 1932, patient returned weighing 135 pounds, having had perfect digestion ever since operation. No pain or jaundice: no sensation of fullness or belching: liver edge still nearly to umbilicus, but edge is sharp and upper border at sixth rib by percussion and is apparently only pitted rather than enlarged now. Patient has urinary symptoms with 2.5 ounces residual urine because of a small fibrotic prostate which will probably require a caustery punch. Following elimination of this source of straining we will repair his inguinal hernia.

SUMMARIES OF CASES

1. A patient aged 37 years, recently jaundiced, had suppression of urine, nitrogen retention, hypertension, positive urine of low specific gravity, no edema but marked diuresis, on recovery. At second admission, following cholecystectomy the urine was of higher specific gravity, hypertension was improved. Cholecystectomy was done. Patient now has developed diabetes mellitus, toxic adenoma of thyroid, hypertension is still present, gastro-intestinal status is excellent.

2. Patient aged 53 years, jaundiced, had suppression of urine, nitrogen retention, increasing blood pressure, positive urine of low specific gravity, edema. She died without operation. Gross autopsy only was done.

3. Patient aged 71 years, jaundiced, had 42 per cent retention of io-iodo-18 in 30 minutes (liver failure) on admission, suppression, nitrogen retention after partial diuresis, positive urine of low specific gravity, edema, low blood pressure, slow pulse. Patient died without operation. Autopsy showed characteristic kidney lesions.

4. Patient aged 53 years, jaundiced, was known to have had normal urine and normal phenolsulphophthalein output 1 month before suppression, nitrogen retention, edema. Urinalysis was not reported. Patient died without operation. No autopsy.

5. Patient aged 61 years, jaundiced, showed positive urine of moderate specific gravity on entrance and slight nitrogen retention 3 days later. Jaundice subsided. One week after cholecystectomy and exploration, common duct developed moderate suppression, nitrogen retention, positive urine, simultaneous with blocking internal bile drainage, cause unknown, and deepening jaundice. Death occurred and no autopsy was obtained.

6. Patient aged 63 years, had never been jaundiced. On admission to hospital with empyema of gall bladder she showed suppression, no nitrogen retention, positive urine, slight hypertension. No function tests were recorded. The output rose after operation. Cholecystectomy was done. Convalescence was normal until he died suddenly from pneumonia on eleventh day. No autopsy was made.

7. Patient aged 37 years, recently jaundiced. Urine was normal and of rather low specific gravity (1.04 highest recorded) and decreasing phenolsulphophthalein output (37.5 per cent) on first admission. Cholecystectomy was done. The phenolsulphophthalein output increased to 53 per cent. Cholecystectomy was done after

lipiodol injections showed patent common duct. Present status revealed definite hypertension (155/95) only partly due to toxic thyroid.

8. Patient aged 64 years, had had a subsiding jaundice of recent origin, with urine practically normal, no nitrogen retention, good phenolsulphophthalein output. Graded operation was chosen because of the age and general weakness of patient since exploration of common duct was indicated. Cholecystostomy was done. On second admission, lipiodol injection was done through a Pezzar catheter and showed a block of the common duct and little alteration in the hepatic tree. Cholecystectomy and choledochostomy (T tube) were withstood. Check up lipiodol injection through T tube showed patent common duct before removal of tube. Present status is excellent.

9. Patient aged 63 years, had very slight subsiding jaundice. The findings were very similar to those in Case 8. Graded operation was done because of weakness and age. Patient lost 25 pounds in weight. Exploration of common duct was indicated. Cholecystostomy was done. Patient was discharged and readmitted for choledochostomy which was well withstood. Present status is excellent.

10. Patient aged 49 years, never had been jaundiced. Urine was normal, no functional test recorded. Staged operation was not planned. Condition became poor on tube after only appendectomy. Present status is excellent. She is still wearing Pezzar catheter. Cholecystectomy is still to be done.

11. Patient aged 64 years, had never been jaundiced. The urine was normal, there was no nitrogen retention, but a moderate anemia. Patient had marked arteriosclerosis, he seemed older than his years. Cholecystostomy was planned and performed. He could not have withstood more. Present status is 75 per cent normal.

12. Patient aged 70, had never been jaundiced. He was admitted to hospital in acute attack of cholecystitis, phenolsulphophthalein output was not recorded, there was nitrogen retention. Urine was positive, no phenolsulphophthalein excretion at first test. Function improved as attack subsided. Permanent cholecystostomy was advised because of his age and so severe an illness. We do not approve of his respiration elsewhere.

13. Patient aged 53 years, was jaundiced in the past. His urine was normal, function good. He was thin and run-down. With gross liver changes present at operation and old extensive adhesions around common duct it was thought unwise to proceed beyond cholecystostomy. This was borne out by his course in the hospital. Present status is excellent.

Cases 14 and 15 are mentioned merely because the lipiodol injection through T tubes in their common ducts illustrate so well the value of this method of outlining the biliary tree. The dilatation of the intrahepatic radicals shows clearly persisting 10 months after plastic operation for stricture in Case 14. The film of Case 15 taken 12 days after choledochostomy shows the same dilatation and prompt emptying of the ducts. If it is desired to outline the biliary radicals in the liver injection through Pezzar catheter in the gall bladder or through the T tube in the common duct should be made with the patient in the Trendelenburg position under the fluoroscope. We had been making such observations for about a year before the publication of

Overholt's preliminary report. The plan is very useful, it is a real addition to our means of following patients with therapeutic biliary fistula. We hope to see the dilatation of the intrahepatic radicals disappear in Case 15 before we remove the T tube for this would be the best evidence of restitution of normal anatomical status. When we have been able to follow with lipiodol injection the course of a larger group now under observation Dr John Young and the author propose to publish the results in full.

Excluding Case 5 which occurred previous to the start of this study 56 patients with diseases of the biliary tract have come under our care. Operation was not performed in 3 (Cases 2, 3, 4). On the remaining 53 patients primary cholecystectomy was performed in 37 cases with exploration of the common duct in 2. There were 2 deaths in this group both of overwhelming pneumonia and septicæmia, one occurring on the sixth, the other on the eighth postoperative day, in women under 40 years both occurred previous to the adoption of carbon dioxide inhalations as routine postoperative care. Cholecystostomy was done as the first step of a contemplated graded operation in 6 patients (Cases 1, 6, 7, 8, 9, 10), followed by subsequent cholecystectomy in 2 (Cases 1, 7) by exploration of the common duct with cholecystectomy in Case 8 and without cholecystectomy in Case 9. Case 10 has not yet had her final operation. The one death in this group occurred in Case 6 pneumonia developing on the fourteenth day after a reasonably smooth postoperative course. Cholecystostomy as the only contemplated operation was performed in 5 patients among whom are Cases 9, 12 and 13. temporary drainage of the gall bladder was instituted in 2 other patients, one being a woman operated on with a diagnosis of perforating ectopic pregnancy and found to have acute appendicitis and a gall bladder full of calculi, the other a man on whom appendectomy was performed in an interval of intermittent appendicitis, the gall bladder being somewhat thickened, without stones but high under the liver and very difficult to reach. Secondary cholecystectomy was performed on 2 patients, one of whom had had a stone left in the cystic duct following cholecystostomy elsewhere 6 months previously, we had performed cholecystostomy on the other patient 9 years previously. In the 3 remaining cases exploration of the common duct for stricture in one case and for stone in the other 2 was performed. The patient with stricture and one of those with stone were jaundiced at the time of operation, they were the only cases of

all the jaundiced patients that bled after operation in spite of the usual preparation with calcium chloride and transfusion of blood.

Until recently there was no clinically useful dye test for liver function. With the introduction of *iso-nodexon*, such a test seems at hand. We do not look for any great reduction in post-operative mortality from its use in our own practice for it is obvious that we have not been operating upon patients with badly failing livers. We feel that wider appreciation of the need for thorough evaluation particularly from the standpoint of the renal anatomical and physiological status, of all patients with biliary tract disease will be more generally effective in reducing operative mortality. Renal insufficiency occurs in such patients in the absence of jaundice, especially in patients in an acute exacerbation. The occurrence of nephritis in them must be laid to infection, and a study of the infecting organism in such cases is especially indicated. *Acute nephritis is uncommon in other diseases of the abdominal viscera amenable to surgical attack.* It is a fact that operations on only the biliary tract are done for chronic intra abdominal infections, with the exception of those on the female pelvis in whom conditions for absorption, localization, and drainage are quite different. (We see little clinical or pathological evidence for the existence of chronic appendiceal infection unmarked by exacerbations recognizable as acute attacks.) We believe that for this reason an unbearable burden is thrown on the kidneys more often in operations on the biliary tract than elsewhere. The point can be forced to an extreme by considering how often nephritis and anuria would occur if patients with scarlatina were given an ether anaesthesia lasting for an hour and subjected to a major operation!

Simply because the barbituric acid compounds are excreted largely through the kidneys, we do not propose to use them as pre-anaesthetic preparation for this group of patients in the future. Where a stage operation has been decided upon, paraldehyde or some other drug excreted through the lungs, can be given by rectum before taking the patient to the operating room. A light nitrous oxide or ethylene anaesthesia should be used to mask the infiltration and blocking of the abdominal wall. Cholecystostomy can then be performed by the technique outlined in the case histories in less than 15 minutes, ordinarily. If an inhalation anaesthetic is required ethylene is preferable to nitrous oxide since any degree of cyanosis threatens all cellular metabolism. Morphine should be used very sparingly for the same reason.

CONCLUSIONS

1. A review of the literature on renal complications of biliary tract disease is given.

2. Six cases of nephritis with suppression of urine complicating biliary tract infections are presented. To these a seventh (Case 12) should probably be added. With one exception (Case 5) these occurred in a series of 56 consecutive patients, an incidence of 10.7 per cent.

3. This complication occurs at times, particularly in acute exacerbations, without jaundice and can be detected in its incipency. Functional tests are discussed.

4. Excretion of phenolsulphonaphthalein in patients in whom primary cholecystectomy or choledochostomy was performed has varied only within the normal range for the age of the individual.

5. There is no evidence that hepatic cell damage serious enough to cause liver failure must precede renal damage though ordinarily the two are associated.

6. Stage operations are advocated for patients who have suffered from renal complication, as well as for all seriously depleted patients with biliary tract disease. Illustrative cases are presented in which cholecystostomy is done as a preliminary step and others in which it is the only operation contemplated.

NOTE.—Since this paper was submitted for publication, an article by Helwig and Schults has appeared, which deserves comment. They regard nephritis as secondary to degeneration of liver tissue, as did some of the early German authors. They correctly note the inconsistency of jaundice as an etiological factor. However their observations and conclusions may be adversely criticized on the following points: (1) They disregard the evidence of active infection in Cases 1, 3, 5 and 6 (exacerbation of symptoms before operation and acute inflammation found at operation) as unimportant in precipitating post-operative renal failure. (2) They describe laboratory findings as being "normal" before operation, which raises the suspicion that a blood non-protein nitrogen determination within normal limits was accepted as evidence of normal kidneys. (3) Their experimental work consisted in producing a limited necrosis of the liver by trauma. The production of acute nephritis by liberation of products of aseptic necrosis of other tissues (as in skin burns and in acute pancreatitis with \pm necrosis) is well known, their experiments are not evidence for specific action of liver necrosis on the kidney parenchyma. (4) They characterize the condition under discussion as "hepato-renal syndrome" which obscures the clear-cut evidence that acute nephritis following infections in the bile passages or destruction of liver tissue (just as after infection in the throat) occurs more frequently than has been previously thought. The statement that the "syndrome" has been previously undescribed is hardly warranted, in view of the literature which they as well as I, have summarized.

I am satisfied that we are both describing the same clinical condition, they disregard the role of infection in the bile passages as being the direct cause of the nephritis.

while I consider it of the greatest etiological importance and believe that a specificity for renal tissue of the toxins of the infecting organisms will eventually be shown.

A recent communication by Cinzberg calls to my attention a previous publication of lipiodol injections through biliary fistulae with very satisfactory results.

THE CENTURY OF PROGRESS

FUR Trading Indians French Wars, Missionaries Cholera, Fort Dearborn The United States Army Emigration from the East Fort Dearborn Massacre, Rail Splitting Primitive Medicine and Midwifery War Wounds Vision Courage Faith Perseverance Foundation of Medical Schools and Societies, Success Such are the chapter headings of the history of Chicago and its environs of a century or so ago.

During the intervening years Chicago has run the gamut of the helps and hindrances of civilization. Its strategic geographic situation and the character of its citizenry have drawn to it everything that goes to make up a metropolitan center of cosmopolitan interests and to establish it as an epitome of world progress.

Forty years ago in Chicago the discovery of America was memorialized by the Columbian Exposition the world's fair after which subsequent world's fairs have been patterned. This year the centennial of Chicago will be memorialized by a Century of Progress a new type of world's fair in which the nations will

co-operate to display the present scientific, religious, and artistic status of the world.

From June 1 to November 1 the beautiful lake front of Chicago will present the forefront of the march of progress in achievement. The very inventions and discoveries of the Century which have brought about the present mechanical age have made it possible to make the displays in a way that was heretofore impossible.

The science and art of the engineering profession have produced changed conditions of life, and the science and art of the medical profession have made life safer better and longer under these new conditions.

The products of the basic sciences of chemistry and physics as exemplified in the conversion of raw materials into articles of utilitarian and artistic value will be exemplified and the leading spirits of the exposition have set a new tempo by emphasis on a display of the processes of manufacture as well as on the finished products.

The use of steam, oil gasoline, and electricity in the production of light, heat and power and the application of these to mining agriculture and manufacture, transportation communication and illumination are products of this last century and so will occupy important places in the exposition.

The artistic side will be interwoven in all phases of the Fair by a new use of color light architecture sculpture and painting.

Of particular interest to the medical profession will be the exhibits on the medical and biological sciences which will receive a prominence not hitherto accorded them in such general expositions. Universities, national

state, and civic medical institutions and commercial organizations will vie with one another and the result cannot but be reflected in a better comprehension of medical and surgical problems by the public. From this will come improved health of the people through a better and surer knowledge of how disease is caused, prevented and cured, and how these benefits may be derived from the medical profession.

The American Medical Association, the American Dental Association, the Wellcome Research Institution, the American College of Surgeons, a number of our universities and large private medical clinics have prepared attractive and instructive exhibits. The following is a brief summary of the exhibit of the American College of Surgeons.

Improvements in surgery in America during the past century will be portrayed by five beautifully executed dioramas. Details of hospitals and their care of the sick and injured during the nineteenth century and today will be depicted by transparencies, models, a semi-diorama, and an illustrated map. A replica of the Lister exhibit in the Wellcome Historical Medical Museum. **SURGERY, GYNECOLOGY AND OBSTETRICS**, the official journal of the College, will exhibit an authentic record of surgical progress. The College activities, surgical progress and service to the public will be described through illustrated lectures. The objects and activities of the College will be further illustrated by illuminated wall plaques. The exhibit will be enhanced by the use of portraits of eminent American surgeons of the century, the Great Mace of the College, the Seal of the College in magnified form, and by other means.

During the period of the Century of Progress Chicago will be host at the annual meetings to a number of the national medical organizations.

ALLEN B. KANAVEL.

SUBPHRENIC INFECTIONS

UNFORTUNATELY the importance of subphrenic infections is not sufficiently appreciated by most surgeons. The majority of subphrenic infections are the result of an intra abdominal contamination usually caused by extension of micro-organisms from an abdominal viscus. Rarely subphrenic infections may extend from extra abdominal foci either by direct extension (from the thorax) or through the blood stream. Only a relatively small percentage of subphrenic infections proceed to abscess formation. By far the larger number resolve spontaneously, which probably accounts for the fact that subphrenic infections without abscess are relatively infrequently diagnosed. The most frequent cause of subphrenic infection is post appendiceal peritonitis. However in all cases of acute peritonitis the possibility of the development of a subphrenic infection must be kept in mind, as in this way the early diagnosis is facilitated. Subphrenic infections following acute appendicitis characteristically are found most frequently in the right posterior superior space viz. above the liver on the right side and behind the right prolongation of the coronary ligament. This infection is manifest clinically by a persistent point of tenderness over the right twelfth rib. An infection inferior to the liver but on the right side i.e. right inferior space infection may occur concomitantly with right posterior superior infections.

The prognosis in subphrenic infections is very good because only relatively few of the infections progress to suppuration. The prognosis in subphrenic abscess has been considered as being especially grave, due to two facts (1) the diagnosis of the infection is made relatively late and (2) most subphrenic abscesses have been drained either transpleurally

or transperitoneally and because of contamination and subsequent infection of one of the large serous cavities (the pleural or peritoneal) an overwhelming and fatal toxemia develops. The mortality rate in collected series of cases varies from 20 to 100 per cent. In the treatment of subphrenic abscess the same surgical principles as used elsewhere in the body should be applied. Whereas it is frequently possible to drain an intraperitoneal abscess through an uninvolved peritoneum by attempting to protect the virgin peritoneum from contamination it is far better to drain the abscess extraperitoneally as the danger of contamination of the peritoneum is thus obviated. Similarly it is far better to drain subphrenic abscesses extraperitoneally in such a way that contamination of the pleural and peritoneal cavities is prevented. In abscesses pointing anteriorly extraperitoneal approach is possible by reflecting the peritoneum from the under surface of the diaphragm until the abscess is encountered. In those abscesses pointing posteriorly the retroperitoneal operation (2) permits adequate exposure and drainage of abscesses in this region without the danger of contaminating either the peritoneal or pleural cavity. The advantage of the extraperitoneal operations over the other methods

of approach is exemplified by Flynn's (1) statistics of cases of subphrenic abscess operated upon by members of the Southern Surgical Association. In those cases in which operation was by the transpleural transperitoneal or extraperitoneal method the mortality rate was 37.9 per cent. In those cases in which operation was by transpleural or transperitoneal routes the mortality rate was 41 per cent. whereas in those cases in which operation was by the extraperitoneal technique the mortality rate was 18.4 per cent. In 10 personal cases operation was by the retroperitoneal operation and there was but one death a mortality rate of 5.2 per cent. (3). In fact it is my firm belief that subphrenic abscesses should be treated successfully with no mortality. This can be accomplished however only by the early recognition of the condition and the institution of adequate drainage without contaminating uninvolved serous cavities. ALTON OGDEN

JOHN SYNG DORSEY
1783-1818

MASTER SURGEONS OF AMERICA

JOHN SYNG DORSEY

FROM time to time in history there have lived men who have been able to accomplish a full life's work within a brief span of years. A man of this mold John Syng Dorsey was able during his thirty-five years of life to reach a prominent place in American surgery of the early nineteenth century. Like his contemporary the great composer Franz Schubert, who lived but thirty-one years, he seemed unconsciously to sense the need for filling every moment so that his successive achievements came with dramatic frequency.

Members of the old English family of Dorsey were early settlers in Maryland, but John was born in Philadelphia in 1783 where his father Leonard Dorsey was a prominent merchant. Young Dorsey passed rapidly through his classical studies at the Friends Academy and the University of Pennsylvania, overcoming the handicap of a slight defect in speech and graduating with distinction at the age of fifteen years. He began at once the study of medicine at the University of Pennsylvania under the guidance of his noted uncle Dr. Philip Syng Physick, who held the chair of surgery at that time. A year prior to his graduation he was honored with a membership in the Medical Society of Philadelphia, Benjamin Rush was then president of the organization. In that same year Dorsey became a member of the Chemical Society of Philadelphia, an organization "desirous of promoting the cultivation of the science of chemistry in the United States of America by associating with themselves persons of distinguished talents." In 1802, at nineteen years of age, he defended his thesis on "The Powers of the Gastric Juice as a Solvent for Urinary Calculi" and received his degree of Doctor of Medicine, a special dispensation from the board of trustees waived the requirement that candidates for the degree must be twenty-one years of age.

Coincident with his graduation occurred one of the severest epidemics of yellow fever in the history of Philadelphia, and young Dr. Dorsey was made resident physician of one of the emergency hospitals. During his year of service there he demonstrated his sincere faith in his own reasoning and convictions. He believed with Devereze that yellow fever was not contagious and fearlessly went about the care of his patients, constantly exposing himself to the disease, whereas many of his confrères who entertained similar ideas were unwilling to vindicate them.

In 1803 Dorsey sailed to Europe for a year of study. The entire winter was spent in London where he attended the lectures of the famous chemist Sir Humphry Davy but spent the most of his time in John Hunter's anatomical school where in former years his uncle Dr. Physick had so distinguished and endeared himself that the great anatomist had made an offer of partnership. Dorsey spent the remaining portion of the year in Paris where he continued his studies in anatomy.

In 1804 Dorsey returned to Philadelphia and prepared to practice his profession. Those first few years must have carried all of the traditional monetary anxiety for his old account books reveal that his income for the first year was only \$3 5 75. However appreciation of his ability spread steadily and in a few years he was considered one of the most skillful surgeons in the country. He was elected to the staff of the Pennsylvania Hospital where the first ligation of the external iliac artery for aneurism was performed by him. It was during this period that he prepared the manuscripts for his great book *Elements of Surgery* a work which received much recognition and was reprinted in Edinburgh as a textbook for the university. The material it contained was drawn partly from his own experience but largely from the experience of his uncle Dr. Physick, to whom the book was really a monument for Dr. Physick left but few writings of his own. Dorsey's talent and training as a draughtsman enabled him to prepare his own beautiful illustrations.

At the age of thirty two Dorsey accepted the chair of materia medica in the University of Pennsylvania and soon endeared himself to his pupils by his tireless interest in their work and the frank sympathetic manner of his teaching. Following the example of Wistar he valued and thoroughly enjoyed informal gatherings with his students where exciting controversies often developed stimulated by his clear direct thinking and youthful enthusiasm. He loved to debate and his discussions at medical meetings always attracted interest often were at variance with current opinion but never were injured by petty meanness or personal rancor. His association with great men abroad and his great love for music and poetry mellowed the brilliance of his scientific fervor and made his character of outstanding appeal.

In 1818 occurred the sudden death of Dr. Caspar Wistar the highly respected and much loved professor of anatomy at the University of Pennsylvania. It was he who had first developed in this country the continental plan of informal discussions between professor and students and it was through his efforts over a long period of years that the teaching of anatomy had reached such a high plane there. John Dorsey was selected to fill the vacant chair a difficult task but one which he accepted with sincere confidence and reverent respect for his predecessor. On November 12 1818 he delivered the introductory lecture to his students. It was an inspiring talk of outstanding richness of thought, carefully designed to lead the

beginners in medicine beyond the unfamiliar horrors of the dissecting room to an earlier realization of the value of true knowledge and a visualization of the long vista of interesting work before them. No oratorical displays of rhetoric or eloquence can aid the anatomist to enliven your attention. he told them "his eloquence is of the hand, his rhetoric of the scalpel! But when the years shall have rolled away and your memory shall be tasked to recall the vestiges of scholastic learning when your teacher's tongue shall be silent and his hand motionless, then the impressions derived through the medium of your senses will be found fresh and vivid long after the collections of impassioned oratory shall have faded from your minds.

The tragic drama of this counsel was to be realized with terrible suddenness. Within a few hours after this Dorsey's first address to his class he was stricken with a fatal illness which proved to be typhus fever. He died ten days later thus ending at thirty five years a career of such achievement as to rank him among the foremost surgeons of his time and of such promise that inevitably he would have been grouped with the great men of all time. LEONARD FREEMAN JR

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

J. BENTLEY SQUIER, New York, *President*

WILLIAM D. HAGOARD, Nashville, *President Elect*

FRANKLIN H. MARTIN, Chicago, *Director-General*

PHILIP H. KREUSCHER, *Chairman* OSCAR E. NADCAU, *Secretary* *Committee on Arrangements*

PLANS FOR THE 1933 CLINICAL CONGRESS IN CHICAGO

FOR the twenty third annual Clinical Congress of the American College of Surgeons, to be held in Chicago October 9-13, 1933, the surgeons of that great medical center are keenly interested and have organized to provide for the Fellows of the College and their guests, a program of surgical clinics and demonstrations that will present a most complete showing of the city's clinical activities in all departments of surgery. In these plans the Committee on Arrangements has been assured of the hearty co-operation of the surgeons of the four medical schools and more than fifty hospitals that will participate in the clinical program.

It will be recalled that the first Clinical Congress was held in this city in 1910 and that out of that meeting largely attended by enthusiastic surgeons from all parts of the United States and Canada, came the organization of the College which this year celebrates its twentieth anniversary.

The Congress will open at 10 o'clock on Monday, October 9, with the annual hospital conference to be held in the ballroom of the Stevens Hotel. An interesting program of papers, round table conferences and practical demonstrations dealing with problems related to hospital efficiency is being prepared for presentation at this conference which will continue on Tuesday and Wednesday. The program is being prepared with a special view to interesting surgeons, hospital trustees, executives, and personnel generally.

Among the outstanding features of this year's session of the Clinical Congress will be: (1) a symposium on cancer under the auspices of the College Committee on the Treatment of Malignant Diseases on Thursday afternoon following the annual meeting; (2) a conference on fractures arranged by the College Committee on the Treatment of Fractures, on Wednesday afternoon.

A preliminary program of clinics and demonstrations is being prepared under the supervision of the Committee on Arrangements for publication in an early issue of this journal. Operative clinics and demonstrations in the hospitals will be scheduled for Monday afternoon, October 9, beginning at 2 o'clock and for the mornings and afternoons of each of the four following days. All departments of surgery will be represented in this clinical program—general surgery, obstetrics, gynecology, urology, orthopedics, and surgery of the eye, ear, nose and throat. Hospitals participating in the program are:

Alexian Brothers	John B. Murphy
American	Oak Park
Angostano	Pennavant Memorial
Albert Albert Billings	Post-Graduate
Chicago Eye, Ear, Nose and Throat	Presbyterian
Chicago Lying In	Ravenwood
Chicago Memorial	Michael Reese
Children's Memorial	Research and Educational
Columbus	St. Anne's
Cook County	St. Anthony de Padua
Evangelical Deaconess	St. Bernard's
Evangelical	St. Francis
Evangelist	St. Joseph's
Garfield Park	St. Luke's

An Executive Committee appointed by the Board of Regents to supervise the development of the clinical program is as follows: Philip H. Kreuscher, chairman; Oscar E. Nadcau, sec-

tary: Joseph Beck, William R. Cubbins, Frederick H. Falls, Harry S. Gradle, Carl A. Hedblom, Charles E. Kahlke, Herman L. Kretschmer, Karl A. Meyer, Dallas B. Phemister, Edwin W. Rye, son and Henry Schmitz. To this group will be added representatives for each of the hospitals co-operating in the clinical program to comprise the local Committee on Arrangements.

Two sub-committees have been appointed to supervise the program for the sections on surgery of the eye, ear, nose and throat as follows: Ophthalmology—Harry S. Gradle, chairman; Thomas D. Allen, E. K. Findlay, Sanford Gifford, Otolaryngology—Joseph Beck, chairman; Austin A. Hayden, Edward P. Norcross, S. J. Pearlman. The recommendations of this committee insure a worth while program of clinics and scientific sessions for all those who are interested in these specialties.

Special features of the clinical program will be (1) Demonstrations at several hospitals of modern methods in the treatment of fractures which form so large a part of the surgical work in large cities and industrial centers; (2) a series of cancer clinics demonstrating the treatment of cancer by surgery, radium and X-ray; (3) clinics in traumatic surgery demonstrating methods of rehabilitation by surgery and physiotherapy of patients injured in industrial, automobile and other accidents.

EVENING MEETINGS

The Central Executive Committee of the Congress is preparing programs for the series of five evening meetings to be held in the grand ballroom of the Stevens Hotel.

At the presidential meeting on Monday evening following the address of welcome by the chairman of the Committee on Arrangements, Dr. Philip H. Kreuscher, the Director General, Dr. Franklin H. Martin will introduce the visiting surgeons from foreign countries, a large number of whom have been specially invited to attend the Congress this year. Following the address of the retiring president, Dr. J. Bentley Squier, of New York, the president-elect, Dr. William D. Haggard of Nashville, Tennessee is to be inaugurated. The John B. Murphy oration in surgery will be delivered at this meeting by Dr. Loyal Davis, of Chicago.

At the annual convocation of the College to be held on Friday evening when the 1933 class will be received into Fellowship in the College the presidential address will be delivered by Dr. William D. Haggard and the Fellowship address by Robert Maynard Hutchins, A.M.

ILL.D. president of the University of Chicago. For the sessions on Tuesday, Wednesday and Thursday evenings distinguished surgeons of the United States and Canada with visiting surgeons from abroad have been invited to present papers dealing with surgical subjects of timely interest. Among the speakers who will present papers are the following: George W. Crile, M.D., Cleveland on Clinical Problems and End Results in the Surgical Treatment of Goiter; Edward D. Churchill, M.D., Boston, Tumors of the Parathyroid Glands; Edward C. Naffziger, M.D., San Francisco, Treatment of Exophthalmos; George E. Brown, M.D., Rochester, Minnesota, Thrombo-Angitis Obliterans; David Edwin Robertson, M.D., Toronto, Sympathectomy in Children.

Arrangements are being made for additional sessions on Tuesday and Thursday evenings at which programs of special interest to ophthalmologists and otolaryngologists will be presented.

HEADQUARTERS—HOTELS

General headquarters for the Clinical Congress will be established at the Stevens Hotel located on Michigan Avenue between Seventh and Eighth Streets. This hotel affords unusual facilities for all activities of the Congress, as will be remembered by those who attended the Congress in Chicago in 1929. The grand ballroom on the second floor with other large rooms on the third floor and the exhibition hall have been reserved for the exclusive use of the Congress. All of the evening sessions, the hospital conference on Monday, the annual meeting, the cancer and fracture symposia will be held in the grand ballroom. The registration and information bureau, together with the bulletin boards on which will be displayed the daily clinical program will be established in the exhibition hall in the basement, together with the Technical Exhibition.

Chicago has many fine, large hotels, several within walking distance of the headquarters hotel. A list of the hotels recommended by the Committee on Arrangements will be published at an early date. While Chicago's hotel facilities are very great and there should be no difficulty in securing first class hotel accommodations, it is advisable for those who expect to attend the Clinical Congress to reserve their hotel accommodations as far in advance as possible as the Century of Progress Exposition will undoubtedly bring to Chicago a very large number of visitors.

The Technical Exhibition of the Clinical Congress will be located in the Exhibition Hall together with the registration and information bur

eau. In the same room will be found the bulletin boards on which the daily clinical programs will be posted each afternoon. The leading manufacturers of surgical instruments, X ray apparatus, operating room lights, hospital apparatus and supplies of all kinds, ligatures, dressings, pharmaceuticals and publishers of medical books will be represented in this exhibition.

We are assured that the railways of the United States and Canada will grant especially low rates on account of the Clinical Congress in connection with the Century of Progress Exposition in Chicago. Applications for reduced fares for this meeting are pending before the various railway traffic associations.

ADVANCE REGISTRATION

The hospitals of Chicago afford accommodations for a large number of visiting surgeons, but to insure against overcrowding the attendance will be limited to a number that can be comfortably accommodated at the clinics—the limit of attendance being based upon the results of a survey of the amphitheatres, operating rooms, and

laboratories of the hospitals and medical schools to determine their capacity for visitors. It is expected, therefore that those surgeons who wish to attend the Clinical Congress in Chicago will register in advance.

Attendance at all clinics and demonstrations will be controlled by means of special clinic tickets, which plan provides an efficient means for the distribution of the visiting surgeons among the several clinics and insures against overcrowding as the number of tickets issued for any clinic will be limited to the capacity of the room in which that clinic will be given.

A registration fee of \$5.00 is required of each surgeon attending the annual Clinical Congress, such fees providing the funds with which to meet the expenses of the meeting. To each surgeon registering in advance a formal receipt for the registration fee is issued, which receipt is to be exchanged for a general admission card upon his registration at headquarters. This card, which is non-transferable, must be presented in order to secure clinic tickets and admission to the evening meetings.
